Sometime in the next 30 years, if projections from the United Nations (UN) prove to be on the mark, the populations of poor countries will cross an historic threshold, becoming for the first time more urban than rural (United Nations 2012). In public health, as in other fields, the full implications of this urban transition are only beginning to be appreciated. Part of the difficulty is that the term ‘urban’ refers to a bewildering variety of environments. The health circumstances of small cities and towns differ in many ways from those of larger cities. Within any given city, some residents live in secure, gated communities having all the amenities of Europe or the United States, whereas others—especially those who live in slums—exist in grim Dickensian settings lacking the most basic of human needs in water supply, sanitation, and housing. The health systems of these cities are also astonishingly varied. An urban system will often present the full array of health providers, ranging from traditional healers, purveyors of drugs in street markets, ill-equipped pharmacists and chemists operating from ramshackle storefronts, and so on up the scale to the most highly-trained of surgeons. Among all urban providers, a high percentage are likely to be engaged in private practice, whether on a full-time or part-time basis, and for this reason urban healthcare is more monetized than rural care. In urban areas, unlike rural, it is not so much the distance to services that presents a barrier to their use, but rather the social, informational, and economic costs of access.

To be sure, the urban–rural contrast should not be overdrawn. Many residents of the developing world live on the peripheries of cities in locations that are arguably neither urban nor rural; circular migration and other social linkages have long connected the two sectors; and the multiplicity of contacts provides opportunities for communicable diseases to pass between them. Although urban health cannot be separated out and studied apart from rural, it may nevertheless be useful to consider the features of urban health environments and behaviour that have a distinctive quality. To draw out these distinctions with proper care and nuance would of course require a book-length treatment. Those seeking more comprehensive accounts of urban health than can be provided here, could refer to the recent US National Research Council report (Panel on Urban Population Dynamics 2003) and to Montgomery and Ezech (2005a, 2005b) and especially Harpham (2007) and Mercado et al. (2007) for reviews.

To convey the scale of the urban health challenge that lies ahead, we provide in the first section of the chapter a sketch of the demographic forces that are reshaping the landscape of low- and middle-income countries (see ‘The demographic context’). We then go on to summarize the urban health differentials that can be identified in data from internationally comparable sample surveys (see ‘The urban burden of disease: overview’). Here we begin by documenting urban–rural differences and proceed to give closer attention to the within-urban inequalities in health. The next section draws out the salient features of the supply side of urban health, with particular emphasis on the money costs and quality of healthcare (see ‘The urban health system’). In the final section of the chapter, we turn to a description of urban health risks that have not been sufficiently appreciated, or which, to be effectively addressed, would require an expansive conception of the role of the public health system (see ‘Urban health risks and risk factors’). Extreme-weather events, such as the damaging storms that are expected to increase in severity as global warming proceeds, are a leading example of such risks.

The demographic context

The urban population of the developing world, estimated by the United Nations Population Division to have been 2.67 billion persons in the year 2011, is projected to increase to 3.92 billion by 2030 and further to 5.12 billion by 2050 (United Nations 2012). These additions to the cities and towns of poor countries will account for nearly 90 per cent of all world population growth over the period. By 2050, according to the projections, almost two-thirds of the inhabitants of poor countries will live in urban areas, with the number of large cities in these countries reaching historically unprecedented levels. As late as 1970 there were only two metropolitan areas in the world—the Tokyo and the New York–Newark agglomerations—with populations of 10 million or more. (Cities of this size are commonly called *mega-cities*.) By 2025, according to the UN forecasts, the low- and middle-income countries alone will contain 29 cities of this size. Even more striking is the number of cities in the 1–5 million range. In 1970 only 73 such cities were found in the developing world, whereas by 2025 the UN projects a total of no fewer than 454 cities in this range.

Forecasts such as these seem to have fostered the impression that most urban dwellers in poor countries live in huge urban agglomerations. This is simply not the case. As Fig. 9.7.1 shows,

Fig. 9.7.1 Distribution of urban population by city size, low- and middle-income countries in 2011.

Source: data from United Nations, *World Urbanization Prospects, The 2011 Revision*, Department of Economic and Social Affairs, Population Division, United Nations, New York, USA, Copyright © 2012.

among all developing-country urbanites, only 9.6 per cent live in mega-cities. By contrast, over five times that number live in the small cities ranging up to a half-million in size. As the Panel on Urban Population Dynamics (2003) has argued, such smaller cities warrant much more attention than they have been given.

These cities are generally less well-provisioned than larger places with basic services such as improved sanitation and adequate supplies of drinking water. Rates of malnutrition and the risks of infant and child mortality can be little different in small cities from what is seen in the countryside. Yet the municipal governments of such cities seldom possess the range of health expertise and managerial talent that can be found in the governments of larger places. As low- and middle-income countries continue to decentralize their political and administrative systems, transferring more responsibilities for service delivery and revenue-raising from national governments and health ministries to the local tiers of government and the local ministry offices, the thinner resources and weaker capabilities of smaller cities will need careful attention (Panel on Urban Population Dynamics 2003). The preoccupation with the largest of developing-country cities in health policy discussions, and the general neglect of small cities, has left unaddressed a wide array of important health concerns.

The urban burden of disease: overview

Because very few low- and middle-income countries maintain reliable vital statistics systems, sample surveys provide much of what is known of urban health in these countries.¹ The two major ongoing survey programmes are the Demographic and Health Surveys (DHS), which has fielded and put into the public domain over 250 surveys since the mid 1980s, and the Multiple Indicator Cluster Surveys (MICS), for which some 100 surveys are now available.² The DHS and MICS surveys are nationally representative, and are designed to provide reliable estimates for the urban sector as a whole. However, the sample sizes are too small to yield reliable

health estimates at the level of individual cities. The DHS and MICS programmes have broad data-collection agendas in which health is only one among many areas of inquiry. This breadth is both a weakness and a strength: while limiting inquiry into specific conditions, it enables health measures to be linked to household economic and social variables, allowing some investigation of the social determinants of health (Marmot 2005; Marmot and Wilkinson 2005).

The survey programmes have focused mainly on women of reproductive age and their children. Men are not always interviewed, and even when they are, it is uncommon for a man to be sought out unless he is the partner of an interviewed woman of reproductive age. Nor are the elderly eligible to be interviewed. As a result, cross-national comparisons of the health of the urban elderly are not yet possible (but see Zimmer and Kwong 2004; Kaneda et al. 2005; Hu et al. 2007; Wong et al. 2006; World Health Organization (WHO) 2007a).

Table 9.7.1 summarizes the health data that are routinely gathered in the course of a DHS and MICS survey. This table presents only the core measures that are almost always collected; a number of surveys have been far more ambitious than the list in the table would suggest. Of course there are limits on what can be learned about health in a survey interview. When they are led through their reproductive histories by a skilled interviewer, women can supply reliable information on infant and child survival, but they are unlikely to give medically meaningful accounts of the causes of death. Adult mortality also presents difficulties for the DHS and MICS survey instruments, given that the women who are the primary respondents are generally no older than 50 years of age themselves. Ingenious attempts have been made to measure maternal mortality via the 'sisterhood' method (Graham et al. 1989), and the DHS and MICS surveys could, in theory, do more along these lines. Obviously, asymptomatic conditions cannot be identified in the course of an interview unless blood or tissue samples are collected or the interviewee undergoes a

Table 9.7.1 Health data routinely collected in the Demographic and Health Surveys and the Multiple Indicator Cluster Surveys

Demographic group	Health data	Gaps
Infants and children	Survival, approximate age at death; vaccination status; recent experience of fever, cough, diarrhoea; height and weight for age (in many surveys)	No reliable cause-of-death information; no detailed account of health-seeking behaviour
Adolescents and women of reproductive age	Knowledge of reproduction, contraception, HIV/AIDS, and sources of contraception and healthcare; detailed data on use of contraception; for recent births, nature and timing of prenatal care, place of delivery and attendance	Induced abortion and aftermath not studied; maternal mortality examined indirectly via 'sisterhood' methods; no exploration of asymptomatic health conditions unless biomarkers are collected
Sources of care	Knowledge of sources of contraception and healthcare; in some cases supplemented with an urban 'community questionnaire'	No systematic inventory of health providers; not obvious whether geographic boundaries effectively define urban accessible care

physical examination. (Collection of biomarker data is becoming more common in the DHS programme, but is not yet the norm.) Even reports on symptomatic morbidities and conditions may be clouded by local understandings of what constitutes disease. The measurement of health-seeking behaviour is also difficult to do well via general-purpose surveys. Although instruments can be designed to retrace the steps leading from problem recognition to treatment, relatively few such surveys of this type have been fielded.

Averages and inequalities

It is commonly believed that in modern-day populations, rural levels of health are worse than urban, and this belief is supported by good scientific evidence. In its analysis of 90 surveys from the DHS programme, the Panel on Urban Population Dynamics (2003) found that on average, the urban populations of poor countries exhibit lower levels of child mortality than rural populations, and similar urban–rural differences were evident across a range of health indicators. HIV/AIDS presents the large exception to the general rule of urban health advantage. As will be discussed later, although the epidemic is penetrating rural areas and may be driving up incidence rates there, prevalence continues to be higher in urban areas, often substantially so. Apart from HIV/AIDS, however, in most low- and middle-income countries the urban advantage in terms of average health levels is too well documented to dispute.

But averages can be a misleading basis upon which to set health priorities. Upon disaggregation, urban health averages can be shown to mask wide within-city differentials, and when these are examined, the urban poor are often discovered to face health risks that are nearly as bad as those of rural villagers and are sometimes decidedly worse. To see the urban situation clearly, two types of disaggregation are needed at a minimum: the urban poor must be distinguished from other urban residents; and among the poor, those living in communities of concentrated deprivation—slums, in the usual shorthand—need to be considered separately from the poor who live elsewhere (Montgomery and Hewett 2005). It is also important to distinguish cities from each other on the basis of their health institutions and personnel, and in terms of the strength of oversight and management that is exercised by municipal and other tiers of government.

The data needed to explore these distinctions are not always available. Demographic surveys will usually allow a country's urban poor to be studied as a group, but seldom provide reliable estimates of health among the poor in any given city, to say nothing of the subgroup of poor residents who live in a city's slums. Although there is good reason to expect deficiencies of health personnel and services in the smaller and less-advantaged cities, the empirical evidence on this point is still very thin. The comprehensive review provided by Dussault and Franceschini (2006) emphasizes urban–rural imbalances in health personnel, but does not differentiate among types of urban areas.

The urban poor

Intra-urban health inequalities—which are all too often overlooked by health and development agencies—are readily apparent in household survey data. Using the DHS surveys mentioned earlier, the Panel on Urban Population Dynamics (2003) estimated all-cause infant mortality for the urban poor, other urban households, and all rural households. The results are summarized in Table 9.7.2. As can be seen, the urban poor face significantly greater mortality risks than other urban residents, although as a rule, rural-dwellers face even higher levels of risk. In a

survey-by-survey comparison of the poor urban and rural infants, this study found that the risks facing the urban poor were significantly lower in about two-thirds of the surveys. However, in 29 per cent of the surveys, poor urban infants faced significantly higher mortality risks than their rural counterparts. (In the remaining surveys, no significant difference existed between poor urban and rural infants.) Hence, even the generalization that urban infant mortality is lower than rural needs to be carefully qualified; much depends on whether the urban poor are separated out in the urban–rural comparisons.

The evidence available does not yet permit broad pronouncements to be made about the relative risks of the urban poor and rural-dwellers that apply irrespective of health measure. The National Research Council study analysed children's height for age—an indicator that summarizes a child's history of nutrition and disease—obtaining the results shown in Table 9.7.3 for children in the age range of 3–36 months. Table 9.7.3's entries are Z-scores, with a value of –100 indicating that a child is one standard deviation shorter, given its age and sex, than the median height of an international reference population. The urban poor are again seen to exhibit worse health than other urban children. When the heights of poor urban and rural children were compared, in almost all surveys (60 of the 67 examined) the poor urban children were found to be significantly taller for their age than were rural children. In the height-for-age measure, evidence of an urban advantage persists even for the urban poor.

As is well known, poor urban dwellers are exposed to substantial risks when their neighbourhoods lack the public health infrastructure needed to safeguard water supply and assure sanitary disposal of waste (UN-Habitat 2003a, 2003b). WHO (2002) estimates that in 2001, diarrhoeal diseases accounted for some 2 million deaths, almost all of which took place in low- and middle-income countries, with unsafe water, inadequate sanitation, and poor hygiene likely implicated in a large percentage of these. In its examination of data from the Demographic and Health Surveys, the Panel on Urban Population Dynamics (2003) demonstrated that urban poverty is associated with a lack of access to piped drinking water and with inadequate sanitation. Table 9.7.4 presents selected findings from this study, again comparing poor urban households with other urban and also rural households. As the table shows, the urban poor are markedly ill-served by comparison with other urban households. Rural households

receive even less than poor urban households by way of water and sanitation services, although they benefit to an extent from lower population densities, which offer a form of natural protection against some communicable diseases.

Investments in public health infrastructure require the mobilization of substantial funds, and although public health authorities can help publicize needs and exert pressure, the key decision-makers are generally located elsewhere in the political-bureaucratic system.³ There are, however, complementary initiatives that lie squarely within the purview of public health. As McGranahan (2007) argues, citing Cairncross and Valdmanis (2006) among others, the literature on water and sanitation has tended to give too little attention to the hygienic and storage behaviours that cause water to be contaminated after it has been drawn from the pipes. Important faecal–oral routes for contamination can be addressed through domestic hygiene interventions, including an emphasis on hand washing especially after defecation, control of flies, and encouragement of safer practices in food preparation and water storage. Cairncross and Valdmanis (2006) assembled evidence showing that behavioural interventions in these areas can achieve substantial reductions in diarrhoeal diseases.

Other important health risks also arise in or near the homes of the poor, with the risks presented by indoor air pollution being increasingly recognized. Recent estimates suggest that worldwide, more than 2 billion people rely on solid fuels, traditional stoves, and open fires for their cooking, lighting, and heating needs (Larson and Rosen 2002). These fuels generate hazardous pollutants—including suspended particulate matter, carbon monoxide, nitrogen dioxide, and other harmful gases—that are believed to substantially raise the risks of acute respiratory infections and chronic obstructive pulmonary disorders. Such fuels are often used by the urban poor, who must cook in enclosed or inadequately ventilated spaces. The health burdens associated with indoor air pollution are likely to fall heavily upon women, who spend much of their time cooking and tending fires, and also afflict the children who accompany them.

The spatially concentrated urban poor

It is not surprising that when poor city-dwellers live in close proximity to each other without the benefit of safe drinking water and adequate sanitation, they face elevated risks from water-, air-, and food-borne diseases. This much has been known since the eighteenth century in the West, well before the mechanisms of disease transmission were understood (Woods 2003). It remains difficult, however, to divide the overall risks facing slum-dwellers into the risks attributable to household poverty, and the additional risks produced by the spatial concentration of poverty in slum neighbourhoods and communities.

Although not definitive on this score, Fig. 9.7.2 is suggestive of the impact of concentrated poverty on child mortality in Nairobi, Kenya. In the slums of Nairobi, child mortality rates, at 150 per thousand births, are substantially above the rates seen elsewhere in that city; slum mortality rates are high enough even to exceed rural Kenyan mortality. The magnification of risk evident in the Nairobi slums may be due to multiple factors: the poor quality and quantity of water and sanitation in these communities; inadequate hygienic practices; poor ventilation and dependence on hazardous cooking fuels; the city's highly monetized health system, which

Table 9.7.4 Percentages of poor urban households with access to services, compared with rural households and the urban non-poor

DHS countries (in region)		Piped water on premises	Water in neighbourhood	Flush toilet	Pit toilet

for the poor delays or prevents access to Nairobi's modern health services; and the transmission of disease among densely settled slum-dwellers.

There are additional factors of a social epidemiological character that are worth considering. Facing health threats from their

unprotected physical environments—with the lack of services being a constant reminder of social exclusion—and lacking the incomes needed to counteract these daily threats, the urban poor may well feel unable to take effective action to safeguard their health. Poor individuals and families may thus lack the sense of

**Fig. 9.7.2** Comparison of child mortality rates (q_0) in the Nairobi slums sample with rates for Nairobi, other cities, rural areas, and Kenya as a whole.

self-efficacy needed to energize their health-seeking behaviour in such difficult environments. Poor communities may be reminded by the absence of basic services that the community as a whole is socially excluded and lacks the political voice needed to bring attention to its plight. At the individual and family level, as we will discuss, social exclusion combined with the daily stresses of poverty may bring on paralyzing fatigue, anxiety, low-level depression, and other expressions of mental ill health. At the community level, the symptoms may be expressed in the weaknesses and fragilities of local community organizations, that is, in the lack of what has been termed 'bonding' social capital.

The urban health system

The concept of 'health system' is a very broad one and bringing definition to it is especially difficult in urban areas, within which a disparate set of health providers serves what is typically a highly diverse population, with core health needs arising in part from the many ways in which the population's subgroups come into contact. The urban health system is itself situated within larger political-economic frames at the country level. In the structural adjustment era of the 1980s and early 1990s, a number of low- and middle-income countries introduced user fees into public-sector care as they undertook broad health sector reforms (Harpham 2007). As discussed earlier, in many of these countries the process of decentralization—a transformation of governance that accelerated in the mid 1990s, and which is in its way as profound as the urban transformation—is reshaping relationships between national, regional, and local governments, with important implications for health service planning, finance, and service delivery. These developments provide the context for our discussion of urban health systems.

A distinguishing feature of urban health systems is the prominence of the private sector. Not surprisingly given the higher average levels of income in urban populations and the income diversity that establishes market niches, private services tend to be much more developed in cities than in rural areas, especially in the larger cities (Dussault and Franceschini 2006). Fee-for-service arrangements are generally characteristic of urban healthcare, whereas rural services are often ostensibly provided free of money cost (or made available for nominal fees) at public health-posts and clinics. Even in Latin America, where health insurance systems are more inclusive than in other low- and middle-income regions, only 20 per cent of the urban poor are covered by insurance (Fay 2005). In the more monetized urban economy, the urban poor without cash on hand can find themselves unable to gain entry to the modern system of hospitals, clinics, and well-trained providers. They may then seek care in other niches of the urban system where less-trained providers make drugs and diagnoses available for affordable fees, and may also pursue traditional practitioners, who can adjust the level and type of payment to the needs of their poor clients.

As the Islam et al. (2006) study has documented for Manila and Indore, India, urban health providers are well aware of the effects of monetization on the health-seeking behaviour of the poor. They see poor clients who, having endured their illnesses until care cannot be put off any longer, finally present themselves in a more debilitated condition than they would otherwise have been. Health providers realize that the poor are likely to abandon

courses of prescribed medication to save on the costs of purchasing medicines, or may economize by buying less than what was prescribed. They are not really surprised when the poor fail to return as requested for follow-ups and assessments of progress.

In very few low- and middle-income countries is it possible for the urban poor to receive subsidized care from for-profit private providers, and generally such subsidies are available only through the private non-profit and public-sector clinics and hospitals. Manila's public-sector subsidy programme provides one instructive example. In this health system, subsidies are made available for the purchase of medicines but supplies are not similarly covered. As one physician said in exasperation,

Sometimes, they say they can ask for discounts or even for free medicines, depending on the [income] class. But in supplies, they cannot. So for instance, they get antibiotics for free [but] if you do not have syringe, how can you provide it? We still ask them to buy syringe to provide for the vaccines. (Islam et al. 2006, p. 52)

As this quotation suggests, stock-outs of medicines and basic supplies such as syringes occur frequently in Manila's public-sector facilities. When they occur, it is left to the patient to find the funds to seek out prescribed medicines and supplies at private pharmacies or other sources. In the Manila case, the lowest tier of the public health system—the *barangay* health centre—is a vital component of the system for the poor, because for various reasons the *barangay* centres are more likely to hold small stocks of some of the subsidized medicines.

As the Manila example illustrates, subsidies for the urban poor often depend on an unsystematic set of arrangements, requiring poor patients and their families to spend time searching and negotiating with what must be a bewildering variety of personnel at scattered locations. As they engage in this form of health-seeking behaviour, the poor can be discouraged by the difficulties of finding affordable transport, inconvenient hours of operation at clinics or health centres, the frequent absence of key staff, and long waits to receive care. In effect, the poor are being asked to invest their own time in the hope of securing reduced money costs of medicines. In a full-cost sense, a subsidy for the poor that exists in theory may prove to be no subsidy at all.

We have emphasized the money costs of healthcare, which clearly discourage the urban poor, but they can also be driven away from the modern health system by the indifference or abuse that they anticipate at the hands of formal sector health workers. For example, a study of urban Zimbabwe described the nature of interactions between nurses and women from the community (Bassett et al. 1997, p. 185) thus:

To community women, the expectation of abrupt or rude treatment was the main complaint about the health services. Community complaints were voiced most strongly in the urban areas, where accusations of patient neglect and even abuse suggested a heightened hostility between the clinic and community in the urban setting. Several explanations for nurse behavior were put forward, chief among them was elitism. . . it is in urban areas that class differentiation is most advanced. [The perspective of nurses differed. For them] overwork and low pay promote the adoption of the attitude of an industrial worker—to do what is required and no more. Most nurses work more than one job, not to get rich but to survive.

As this quotation suggests, much of the literature emphasizes the social distance between providers and their patients, the formal language that providers can use to reinforce their own status,

and the possibilities for rude or abusive behaviour on the part of staff towards poor patients. But the literature has not much stressed how difficult it is, even for the most well-intentioned and diplomatic health provider, to get basic information across to poor, illiterate, and possibly intimidated patients. As a Manila obstetrician-gynaecologist explained (Islam et al. 2006, p. 54):

I guess for 90% of our patients, it is us who tell them things. Although there are some who are really inquisitive especially those who have had some education. [But among the urban poor?] They just accept everything we tell them. They rarely ask questions. And sometimes it is difficult to relate to them. They have a hard time understanding what we are saying, even if we use the most basic words or terms. Like for instance, sometimes, we tell them, this is the right way to take the medicine, to make sure that they understand us, we ask them to demonstrate. [Are they receptive to that?] Some, yes. But the others just don't care. They don't know anything, they don't even know when was their last period, family history, nothing. It's really frustrating.

When the poor do succeed in receiving formal healthcare, is that care likely to be of sufficient quality to make an effective difference to their health? An urban quality-of-care study in New Delhi raises serious doubts on this score (Das and Hammer 2007a, 2007b). The study was set in both slum and non-slum neighbourhoods, covering a range of income levels. A full inventory was made of the health providers who serve these neighbourhoods; it revealed that a 15-minute walk would bring a typical neighbourhood resident within reach of 70 health providers of some sort. Even for the poor, access in the sense of geographic distance was not the problem in this case; and if anything, the Delhi poor tended to seek care for illness at least as often as the non-poor. The study assessed the quality of healthcare provision in two ways: via a series of vignettes measuring provider knowledge of the steps to take in making a diagnosis and prescribing treatment or referral (rating the provider responses in relation to examination protocols); and by a follow-up in which many of the same providers were observed as they interacted with patients.

The study found that the quality of care available in the poor neighbourhoods was so low that the authors could fairly describe it as 'money for nothing'. Both public-sector and private providers serve the poor neighbourhoods of Delhi, and both know less about appropriate care than the providers who practise in better-off neighbourhoods. (Levels of health provider knowledge were low across all study neighbourhoods, but were especially low in the poor neighbourhoods.) Evidently, the Indian public sector does not see to it that its more competent providers are allocated to the poor neighbourhoods where they are needed most. When later observed as they interacted with patients, healthcare providers generally asked even fewer questions and exerted even less effort in examinations than their vignettes had suggested they would. In short, it would seem that even strenuous health-seeking efforts on the part of the New Delhi poor would bring them no assurance of reasonable quality healthcare.

Mayank et al. (2001), who studied poor urban women in Dakshinpuri, another New Delhi slum, found that local antenatal clinics did little to provide pregnant women with information about the risks of pregnancy and childbirth. A number of pregnant women suffered from potentially serious ailments—over two-thirds were clinically diagnosed as anaemic, and 12 per cent were found to be seriously anaemic. Yet relatively few understood

that high fevers and swelling of the face, hands, or feet might be symptoms of conditions that could endanger their pregnancy. Fewer than 10 per cent of women attending the local clinic were given any advice about the danger signs of pregnancy. Perhaps it is not altogether surprising that the maternal mortality rate in this urban sample was estimated at 645 deaths per 100,000, a rate not much different from that prevailing in rural India.

Fig. 9.7.3 shows that low quality of care is generally characteristic of urban India (Fig. 9.7A) and is also a concern in the urban areas of the Philippines (Fig. 9.7B). The figure depicts the percentage of women who, in one or more prenatal care visits, were warned of the complications of pregnancy. Among poor urban Indian women, not even 40 per cent are told during prenatal visits of the danger signs of pregnancy. Although the percentages are somewhat higher in the urban Philippines, less than half of poor

Fig. 9.7.3 Information on pregnancy complications given during prenatal care, by relative poverty. Women with one or more visits, urban India and urban Philippines. (A) Women informed of complications and their danger signs during pregnancy, urban India. (B) Women informed of complications and danger signs during pregnancy, and told where to seek care if these appear, urban Philippines. women are informed of the risks and fewer still are told where to seek care if signs of danger surface.

Urban health risks and risk factors

In this section we turn attention to specific urban risks and causes of mortality and morbidity. Several themes unite this material. First among them is the importance of disaggregation of urban health conditions and risk factors by poverty and place. A second and closely-related theme is that of urban social epidemiology, with emphasis on the concepts of individual and collective efficacy in health-seeking. A third theme in the discussion concerns health conditions or risks that are sometimes overlooked, or which are not as well integrated as they might be in urban public health policies. Mental health is perhaps the leading example of such a condition. It is closely associated with poverty and with the health threats that arise from violence and alcohol abuse, which place disproportionate burdens on women. Other examples include the burdens of illness and death stemming from road traffic accidents and outdoor air pollution. In many countries HIV/AIDS already occupies a prominent place on the urban health agenda, whereas urban tuberculosis and malaria receive less attention. The risks stemming from flooding and other extreme-weather events also call for action across a range of actors in government and civil society. Only the most expansive public health programmes in low- and middle-income countries have conceived of the field of action in such broad terms as to encompass all these areas.

To bring some order to a wide-ranging discussion, we begin with an overview of urban causes of death and disability, drawing upon data from Mexico, one of the few low- and middle-income countries that can provide reliable information. With this as background, we then present a series of remarks on the specific features of urban health that warrant closer study.

The urban burden of disease

Table 9.7.5 shows the 15 leading causes of disability-adjusted life years (DALYs) lost in rural and urban areas for Mexico. Several lessons can be extracted from this table. First, urban areas do not necessarily present health profiles that are wholly distinct from those of rural areas. In Mexico, the causes of DALYs lost are much the same in urban and rural areas, although they follow a different rank order. Of the top five causes in Mexico's urban areas, three (deaths related to motor vehicles, homicide and violence, and cirrhosis) are also found among the top five in rural areas. Second, interventions to address two of the most important causes of death and disability in urban Mexico—traffic-related deaths and injuries—would in many countries be considered outside the scope of the public health system. Third, the table reminds us that even in a middle-income country such as Mexico, diarrhoeal disease and pneumonia continue to be important causes of urban death and disability—here as elsewhere, an epidemiological transition is underway whereby the burden of disease is tilting towards non-communicable causes, but this transition is evidently far from being complete.

Table 9.7.5 Disability-adjusted years of life lost in Mexico by cause and residence (1991 estimates, expressed per 1000 population)

Cause	Rural	Rural rank	Urban	Urban rank	Rural/urban
Diarrhoea	12.0	1	2.8	9	4.28
Pneumonia	9.3	2	3.9	7	2.39
Homicide and violence	9.2	3	7.4	2	1.23
Motor vehicle-related deaths	7.9	4	8.3	1	0.95
Cirrhosis	7.5	5	6.3	4	1.19
Anaemia and malnutrition	6.8	6	2.4	11	2.86
Road traffic accidents	5.5	7	6.8	3	0.81
Ischaemic heart disease	5.1	8	5.3	6	0.96
Diseases of the digestive system	4.7	9	1.7	15	2.74
Diabetes mellitus	4.1	10	5.7	5	0.72
Brain vascular disease	3.0	11	3.0	8	1.02
Alcoholic dependence	3.0	11	1.9	13	1.56
Accidents (falls)	2.8	13	2.6	10	1.09
Chronic lung disease	2.6	14	1.9	13	1.39
Nephritis	2.2	15	2.2	12	1.01

Mental health

Mental health as such does not appear in Table 9.7.5, but it is arguably a central factor in the health of the urban poor, and one whose contribution to the urban burden of disease has been under-appreciated. Over the past decade, the WHO has issued a series of reports emphasizing the importance of mental health in developing as well as developed countries (WHO 1996, 2001, 2005a). In a recent review, Prince et al. (2007, table 1) summarized the WHO burden-of-disease estimates for mental health in low-income and middle-income countries. In these countries, mental ill health accounts for roughly 24 per cent of all DALYs lost to non-communicable diseases. For reasons to be described shortly, this figure is likely to understate the full impacts of mental health. Yet, as the authors noted, 'Despite these new insights, ten years after the first WHO report on the global burden of disease, mental health remains a low priority in most low-income and middle-income countries' (Prince et al. 2007, p. 860).

Community-based studies of mental health in low- and middle-income countries suggest that 12–51 per cent of urban adults suffer from some form of depression (see 16 studies reviewed by Blue (1999)). Anxiety and depression are typically found to be more prevalent among urban women than men and are believed to be more prevalent in poor than in non-poor urban neighbourhoods (Almeida-Filho et al. 2004). In a study of Mumbai, Parkar et al. (2003) give an evocative account of the stresses that affect men and women in a slum community just north of the city. Men in this community are deeply frustrated by the lack of work, and this is reflected in a high incidence of alcoholism and violence directed at their wives. Although less is known about mental health among adolescents in low- and middle-income countries, recent studies indicate that this age group also warrants attention. Harpham et al. (2004) made use of the WHO's short-form, self-reporting questionnaire—a bank of 20 items designed to detect depression and anxiety—to study the mental health of adolescents in Cali, Columbia. Girls were found to be three times more likely than boys to exhibit signs of ill health (as Prince et al. (2007) note, among adults the female–male ratio is typically 1.5–2.0) and further multivariate analysis showed that low levels of schooling, within-family violence, and perceptions that violence afflicts the community were all significantly associated with mental ill health among adolescents.

There are two avenues by which an individual's mental ill health might affect other dimensions of health. First, it has been hypothesized that socioeconomic stress undermines the physiological systems that sustain health. Prince et al. (2007, panel 2) emphasized the effects of depression on serotonin metabolism, cortisol metabolism, inflammatory processes, and cell-mediated immunity; they also note that mental disorders are implicated in a range of behaviours (e.g. smoking, poor diet, obesity) that raise the risks of other diseases. Boardman (2004), McEwen (1998), Steptoe and Marmot (2002), and Cohen et al. (2006) provide supportive evidence, although Hu et al. (2007) were sceptical of the hypothesized link from poverty to socioeconomic stress to cortisol metabolism, finding little evidence for it in their large sample of Taiwanese elderly. The possibility of such adverse spill-over effects from an individual's mental ill health to other areas of health, and the need for a full accounting of these effects in calculating the disease burden stemming from

mental disorders, is the principal theme of the comprehensive review by Prince et al. (2007).

The second avenue needing exploration also involves spill-over effects, but in this case the posited linkage would connect women's mental health to the health-seeking energies they can deploy on behalf of their children and other family members. To judge from the review by Prince et al. (2007, p. 867), very little research has been conducted on how mental health affects women's health-seeking behaviour. A few studies have linked mental ill health to the difficulties that individuals face in adhering to their own treatment regimens, especially the demanding protocols required in antiretroviral therapies for HIV/AIDS and directly-observed treatments, short-course (DOTS) for tuberculosis. A bit more attention has been given to the associations between a woman's mental health and her reproductive health, and between the health status of pregnant women and their children's birth weights, with the latter possibly involving health-seeking behaviour. But almost nothing seems to have been written on whether and how mental ill health undermines the sense of self-efficacy that motivates a woman to seek healthcare for others in her family. This is a surprising gap in the literature, especially in view of the well-documented role that women play in protecting the health of their families and the equally common finding that mental ill health is more common among women than men.⁴

Intimate partner violence and alcohol abuse

Violence in urban areas takes a variety of forms, ranging from political and extra-judicial violence to gang violence, local violent crime, and abuse taking place within the home. Moser (2004, tables 1 and 2) developed a framework within which these complex forms of violence can be analysed and described the points of intervention within the judicial, public health, and other urban systems (also see Winton 2004). Garrett and Ahmed (2004) have developed a module for measuring aspects of crime, violence, and physical insecurity that could be adapted for use in surveys, so that these problems can be better documented than they are at present. Our discussion will mainly be concerned with intimate partner violence and its links to alcohol abuse and women's mental health. Heise et al. (1994) reviewed community-based data for eight urban areas from different regions of the developing world, finding that mental and physical abuse of women by their partners was common, with damaging consequences for women's physical and psychological well-being. Using data collected from a module included in several DHSs, Kishor and Johnson (2004) examined whether women had ever been beaten by a spouse or partner. In Cambodia, 18 per cent of women had been beaten, and the percentages in the other study countries were also high: Columbia (44 per cent), Dominican Republic (22 per cent), Egypt (34 per cent), Haiti (29 per cent), India (19 per cent), Nicaragua (30 per cent), Peru (42 per cent), and Zambia (48 per cent). In seeking to understand why women who were the victims of violence did not seek help from the authorities or others outside the home, this study found that embarrassment was a major reason given by women, as well as the belief that it would be futile to seek care or that partner violence was simply a part of life. In some countries (but not in all), poor women were more likely than other women to have experienced violence at the hands of their spouses or partners. Where the connection could

be explored, strong links were also found between spousal alcohol abuse and violence.

These findings were echoed in the WHO (2005b) study summarized in Fig. 9.7.4, which covered both urban and rural study sites. The WHO analysis also documented a close association between the experience of violence and women's mental health. Among the women in this study's Bangladeshi urban site who had been abused by their partner, some 21 per cent had had thoughts of suicide, as against only 7 per cent of women who had not been abused. In all but one of the sites in the study (Brazil, Namibia, Peru, Tanzania, and Thailand), the difference in this measure of mental health was statistically significant, and the ratios are on the order of 2:1 or higher.

Other forms of urban violence also merit attention. Crime is particularly prevalent in Latin America's large cities, where it disproportionately victimizes men living in low-income neighbourhoods (Barata et al. 1998; Grant 1999; Heinemann and Verner 2006). Data collected between 1991 and 1993 in São Paulo suggested that men aged 15–24 in low-income areas were over five times likelier to fall victim to homicide than were men of the same age in higher-income areas (Soares et al., cited in Grant 1999). South African cities also exhibit extraordinarily high rates of violent crime (Stone 2006).

A need exists for systems that can provide women and the poor with some protection from the varied forms of urban violence to which they are vulnerable within and outside the home. To create such systems will require new partnerships linking agencies across urban sectors. In the transport sector, for example, there is a need to make safe the areas where the poor wait for buses and jeepneys; the health sector also has a role to play in security, in that public latrines can be places of risk especially for women; and the authorities responsible for electrification and road construction need to attend to the unlit paths and lanes within slums, a concern for the poor who must commute in the early morning hours or late at night. Effective partnerships against crime and violence involve the formulation of community-driven violence-prevention strategies and the initiation of dialogue between community groups

and the police. (The police may initially resist efforts to involve them in this way, complaining of having to be 'social workers' as well as policemen.) Creation of safe spaces is especially high on the policy agenda for adolescent girls and boys (Erulkar and Matheka 2007).

Reproductive health

The Panel on Urban Population Dynamics (2003) provides a lengthy discussion of reproductive health among urban women, and here we select only a few points for emphasis. Among all urban women, those who are poor are significantly less likely to use modern contraception to achieve control over their family-building (see Table 9.7.6). They are generally more likely to use contraception than rural women, but in some regions of the developing world there is little to separate the two groups. The unmet need for modern contraception—this is measured by the proportion of women in a reproductive union who say that they want to prevent or delay their next birth, believe themselves to be capable of conceiving, and yet do not make use of modern contraception to achieve their stated aims—is markedly higher among poor urban than other urban women.

As the Panel on Urban Population Dynamics (2003) discusses, it is not clear that even when they use modern contraception to prevent conception, urban women do so in an effective manner. Although quantitative estimates are limited to selected case studies, unintended pregnancy and induced abortion are evidently not uncommon for urban women.⁵ To cite a few examples: women in three squatter settlements in Karachi, Pakistan, were estimated to have a lifetime rate of 3.6 abortions per woman (Jamil and Fikree 2002). Another study found abortion to be widespread in Abidjan, Côte d'Ivoire, where abortion is illegal yet nearly one-third of the women surveyed who had ever been pregnant had had one (Desgrées du Loû et al. 2000). A recent study of Ouagadougou, Burkina Faso by Rossier (2007) estimated an annual abortion rate of 4 per cent among women aged 15–49 years, suggesting that over a reproductive lifetime, a woman would have 1.4 abortions on average. Calvés (2002) studied women in their 20s living in

Fig. 9.7.4 Experience of physical or sexual violence by an intimate partner since age 15, among ever-partnered urban women.

Yaoundé, Cameroon. Of these young women, 21 per cent reported having had an abortion; just over 8 per cent had had more than one. Once again, the fact that modern contraceptive services are available in urban areas does not imply that women, especially poor women, have the knowledge and the social and economic wherewithal to make effective use of the methods.

Maternal mortality risks offer another revealing view of urban reproductive health. Because it is difficult to predict whether life-threatening problems will emerge in the course of a woman's pregnancy, delivery, and the aftermath, the prevention of maternal mortality depends crucially on fast access to emergency care. It might be thought that cities, which offer many more transport options than do rural areas, would exhibit much lower levels of maternal mortality. The cases in which the expected urban advantage does not emerge are therefore instructive about the circumstances of the urban poor. Fikree et al. (1997) compared maternal mortality rates in the low-income communities of Karachi with rates in six rural districts elsewhere in Pakistan. While the estimate of maternal mortality ratios for Karachi was the lowest among all these sites, the rural estimates are significantly higher than Karachi's only for the remote districts of Loralai and Khuzdar. It appears that Karachi's poor suffer from maternal health disadvantages not unlike those that afflict Pakistan's rural dwellers.

Why did the urban health advantage not prove greater in this case? In the poor communities of Karachi, some 68 per cent of births are delivered at home and 59 per cent are attended by traditional birth attendants (TBAs). Yet rural women are even more likely to deliver at home and to have family members or TBAs in attendance. Another study of Karachi slums (Fikree et al. 1994) identified the core of the problem: when acute pregnancy and delivery complications arise in these communities, there can be critical delays in locating male decision-makers and obtaining their consent to hospital care. (It has not been customary for husbands or other men to be present at the time of childbirth.) Delays in initiating the search for care are compounded by the tendency for poor Karachi families to pursue local care first, going from place to place in the neighbourhood before making an effort to reach the modern health facilities located outside the neighbourhood. Fikree et al. (2004) has illustrated similar care-seeking patterns in a study of postpartum morbidities in the Karachi slums.

HIV/AIDS

An enormous literature is now available on the social epidemiology of HIV/AIDS in both developing and developed countries. Despite the quantities of research underway on HIV/AIDS, much remains to be learned about its social components. Indeed, although HIV/AIDS is commonly thought to be more prevalent in urban than rural areas, until recently the scientific basis for this belief has been thin (UNAIDS 2004, p. 31). In only a few low- and middle-income countries are community-based studies of prevalence now available that can quantify the urban–rural differences.⁶ For example, findings from several nationally representative community-based studies in which prevalence is estimated from blood samples taken in connection with a DHS survey, show that for Mali, Kenya, and Zambia, urban prevalence rates are clearly much higher than rural rates. The estimated percentage with HIV in urban and rural areas in Mali was 2.20 and 1.50 respectively; for Kenya 10.00 and 5.60 respectively; and for Zambia 23.10 and 10.80 respectively.⁷ Where HIV/AIDS is concerned, there is little evidence of the 'urban advantage' that is seen in other domains of health. However, circular and urban-to-rural migration is contributing to the spread of disease in rural areas (UNAIDS 2004, p. 33), and many observers foresee an era of rising rural incidence and prevalence.

Because the community-based studies are relatively recent, the role played by urban poverty in the risks of HIV/AIDS in low- and middle-income countries is only beginning to be studied. Using the community surveys conducted under the DHS programme, Mishra et al. (2007) found that contrary to expectation, HIV prevalence is higher among the better-off families. These families were more likely to live in urban areas, which accounts for a part of the association, and other risk factors (including sexual risk-taking, use of condoms, and male circumcision) tended to mask the association between living standards and prevalence. Even with statistical controls for such factors in place, a positive association between living standards and HIV prevalence persisted. In studies of urban adolescents and other selected socioeconomic groups, however, poverty has been linked to higher HIV prevalence as well as to a number of contributing risk factors, including earlier sexual initiation and more reported forced or traded sex, which would seem to place poor women at higher risk of contracting the virus (Hallman 2004). In short, the association with living standards is still a matter of dispute.

Tuberculosis

Tuberculosis is even today among the leading causes of death for adults in low- and middle-income countries, killing an estimated 1.6 million people worldwide in 2005 (WHO 2007b). Much as in the nineteenth century, urban crowding increases the risk of contracting tuberculosis (van Rie et al. 1999), and high-density, low-income urban communities may face elevated levels of risk. The interactions between HIV/AIDS and tuberculosis, and the spread of multidrug-resistant strains of the disease, have generated fears of a global resurgence of tuberculosis and have caused WHO to expand its programme beyond DOTS as such.

The concept of urban collective efficacy is directly relevant to the DOTS strategy, the core of WHO's treatment strategy. In a study of tuberculosis in urban Ethiopia, Sagbakken et al. (2003) showed how the local social resources of urban communities

(organized in 'TB clubs') can be marshalled to reduce the stigma associated with the disease and encourage patients to adhere to the demanding short-course regimen of treatment. Similar interventions have been fielded in urban India, as described by Barua and Singh (2003), using community health volunteers to identify local residents with symptoms of tuberculosis and referring them to hospitals for diagnosis; local health workers attached to the hospitals then provide follow-up care and lend support during treatment. An elaborate system of care, involving multiple urban community and health service associations in Lima, Peru, is described by Shin et al. (2004). As reported by the WHO (2007b, p. 78), Bangladesh has made urban DOTS a focus in a programme that links non-governmental organizations (NGOs), private practitioners, medical colleges, and the corporate sector. As the country profiles presented in WHO (2007b) make clear, a number of countries have yet to reach WHO's treatment success rate target of 85 per cent of identified patients, and although data are scarce, it is very likely that detection rates of tuberculosis among the urban poor are well below rates for other urban residents.

Urban malaria

Although malaria has often been regarded as a problem afflicting rural populations, and rural rates of transmission are known to be markedly higher than urban rates, there is clear evidence that malaria vectors have adapted to urban conditions in sub-Saharan Africa (Modiano et al. 1999) and some evidence suggestive of urban risks has emerged for parts of Asia as well. As Hay et al. (2004) argue, urban population growth in South East Asia, as well as sub-Saharan Africa, may be contributing substantially to the global burden of malaria morbidity. Keiser et al. (2004) calculate that in urban sub-Saharan Africa, some 200 million city dwellers face appreciable risks of malaria, and they estimate that 25–100 million clinical episodes of the disease occur annually in this region's cities and towns. Indirect estimates suggest wide variations in prevalence by site, even within small geographic areas, with higher prevalence in the suburbs and city peripheries (especially when these are adjacent to wetlands) than in city centres.⁸

Pictet et al. (2004) describe a recent urban intervention programme mounted in Ouagadougou, Burkina Faso's capital, which aimed to make use of the social resources of urban communities to provide care in uncomplicated cases of child malaria. Inspired by a rural programme that yielded good results, this urban programme enlisted local community residents ('health agents'), gave them training in the recognition of malarial symptoms in young children, and supplied the agents with packets of chloroquine and paracetamol in age-appropriate doses. (In Ouagadougou, a high fraction of malaria cases still respond to chloroquine, although the parasite's resistance is evidently growing.) In cases of childhood fevers, it has been common practice for residents of the Ouagadougou slums to buy chloroquine tablets (or drugs that have a similar appearance) in local markets, using these to medicate their ill children. Preliminary research showed, however, that the residents had little knowledge of the dosages or lengths of treatment appropriate for children. Hence, when judged against the medication practices that were already prevalent in these communities, the programme intervention was expected to improve the standard of malaria care.

When pilot-tested in two communities in Ouagadougou, the malaria intervention showed the expected positive results in the

lower-income community, which was located on the fringes of the city and somewhat isolated from sources of modern healthcare. Of the two study communities, this was the more homogeneous in social and economic terms, and it exhibited evidence of greater 'neighbourliness' and other forms of social interaction through which information about the intervention might have circulated. In the other pilot community, however, easier access was already available to modern health clinics and reputable pharmacies, and more residents could afford to pay for their own care. In this middle-income site it proved difficult to sustain community interest in the intervention. As this Ouagadougou example shows, urban health interventions can be designed so as to tap the social energies and social organization of local neighbourhoods and communities, but the design may need to be tailored to fit the specific circumstances of each such community.

Traffic-related injuries and deaths

We now broaden the discussion to encompass sectors that have not always been linked to or carefully integrated with urban public health programmes, yet which have significant implications for health. Injuries and deaths from traffic accidents are a prominent case in point. Table 9.7.5 for Mexico shows just how important these are among all urban causes of death and disability, but the great range of factors involved—touching on engineering concerns and urban planning and land-use policies as well as individual behaviour—seem in many countries to have inhibited the public health sector from taking action. The scale of this public health problem is enormous: the WHO (2004) estimates that road traffic injuries lead to 1.2 million deaths annually and an additional 20–50 million non-fatal injuries, the majority of which occur in low- and middle-income countries. Two recent discussions—World Bank (2009) and Marquez and Farrington (2013)—highlight the importance of road traffic injuries among all urban non-communicable risks.

To elucidate the factors involved, Híjar et al. (2003) conducted a detailed analysis of pedestrian injuries in Mexico City, where pedestrian death rates are estimated at three times those of Los Angeles. Using a mix of spatially-coded quantitative data and qualitative methods, these authors developed portraits of drivers and victims that underscore the importance of several mutually reinforcing risk factors: poverty, a lack of understanding of how drivers are apt to react to pedestrians, inattention by drivers and pedestrians alike to risky conditions, insufficient public investment in traffic lights and road lighting, and dangerous mixes of industrial, commercial, and private traffic. Bartlett (2002) draws on hospital- and community-based studies to show how poverty and gender affect the risks, and how the time pressures on urban parents limit the effort they can devote to closely supervising their children.

In seeking to raise the public health profile of these important causes, the WHO (2004, 2007d) has given particular emphasis to the risks that are faced by adolescents and young adults, among whom road traffic injuries rank (worldwide) in the top three causes of death in the ages of 5 to 25 years (WHO 2007d, p. 3). In the WHO's Africa region, it is pedestrians (especially children aged 5–9) who face the greatest risks, whereas in South East Asia, the deaths occur disproportionately to riders of bicycles and motorized two-wheelers, who are aged 15–24 years. Fig. 9.7.5 shows how in poor countries of Asia, it is the vulnerable road users—pedestrians,

Fig. 9.7.5 Composition of road traffic injuries by type, selected developed countries and Asian low- and middle-income countries.

Reproduced with permission from World Health Organization, *World report on road traffic injury prevention*, Copyright © World Health Organization 2004, available from <http://whqlibdoc.who.int/publications/2004/9241562609.pdf>.

bicyclists, and operators of motorized two-wheelers—who bear a greater share of the injury burden than the occupants of cars, vans, and buses. For adolescents, young adults, and children alike, males face greater risks than females.

The full package of interventions known to be effective in high-income countries has typically not been implemented in low-income countries (World Bank 2009; Marquez and Farrington 2013). The interventions include behavioural interventions—the promotion through media campaigns and other public health communication outlets of seat-belt use for adolescents and adults and appropriate restraints for infant and child passengers, and encouragement for bicycle and motorcycle riders to wear helmets—as well as traffic engineering concerns, such as the need to remove ‘unforgiving’ roadside objects, properly maintain existing roads, and situate new ones so that high-speed traffic is not routed through densely settled communities or placed near busy markets, schools, and children’s play-spaces. In many low- and middle-income countries, only meagre resources are allotted to traffic control and enforcement of speed and road safety laws. Public health planners will also need to assess the priority that has been given to emergency rescue services (which may involve connections between the health system and the police) and the availability of pre-hospital care and in-hospital trauma centres.

Outdoor air pollution

Traffic and vehicular regulation are also key factors in outdoor air pollution. The Latin American literature is especially rich in scientific analyses of outdoor urban air pollution and its effects on respiratory illness via the intake of airborne particulates and other pollutants emitted by industry and vehicles. Ribeiro and Alves Cardoso (2003) provide a thorough review of such studies for São Paulo; for Mexico City, Santos-Burgoa and Riojas-Rodríguez (2000) have assembled and reviewed a great range of studies. There is increasing interest in the problem in India, China, and other rapidly-developing countries of Asia, where the effects of

economic growth are readily apparent in levels and severity of outdoor air pollution.⁹ In Delhi, a crucial public health intervention was recently made by the Supreme Court in a decision that mandated conversion to compressed natural gas for bus, taxi, and other fleets of vehicles. There is reason to think that on a per-vehicle basis, this intervention has been effective; however, because the total volume of traffic has increased in Delhi, it is not yet obvious that the total volume of particulates and other pollutants has decreased (Kumar 2007; Narain and Krupnick 2007).

Extreme weather events and climate change

Among the extreme weather-related events that put the health of urban dwellers at risk, two deserve particular mention here: the problem of flooding and, at the other end of the spectrum, the problem of water scarcity. Flooding can be characterized as a sudden-onset extreme event; it has afflicted both coastal and inland cities, with many cities inundated on a seasonal or periodic basis. As global warming proceeds, increases in sea level, rising sea surface temperatures, and the mounting likelihood of heavy precipitation will combine to put large urban populations at greater risk. The risks are already readily apparent in Asia, many of whose largest cities are located in the flood-plains of major rivers (the Ganges–Brahmaputra, Mekong, and Yangtze rivers) and in coastal areas that have long been cyclone-prone. Mumbai saw massive floods in 2005, as did Karachi in 2007 and again in 2010. Fig. 9.7.6 depicts Asian cities at risk of both inland and coastal flooding. Flooding and storm surges also present a threat in coastal African cities (e.g. Port Harcourt, Nigeria, and Mombasa, Kenya) and in Latin America (e.g. Caracas, Venezuela).

Excellent accounts of the health consequences of flooding include Portier et al. (2010), Ahern et al. (2005), Shultz et al. (2005), ActionAid International (2006), and Kovats and Akhtar (2008), with an authoritative summing-up in a recent Intergovernmental Panel on Climate Change report (2012). Urban flooding risks in poor countries stem from a number of

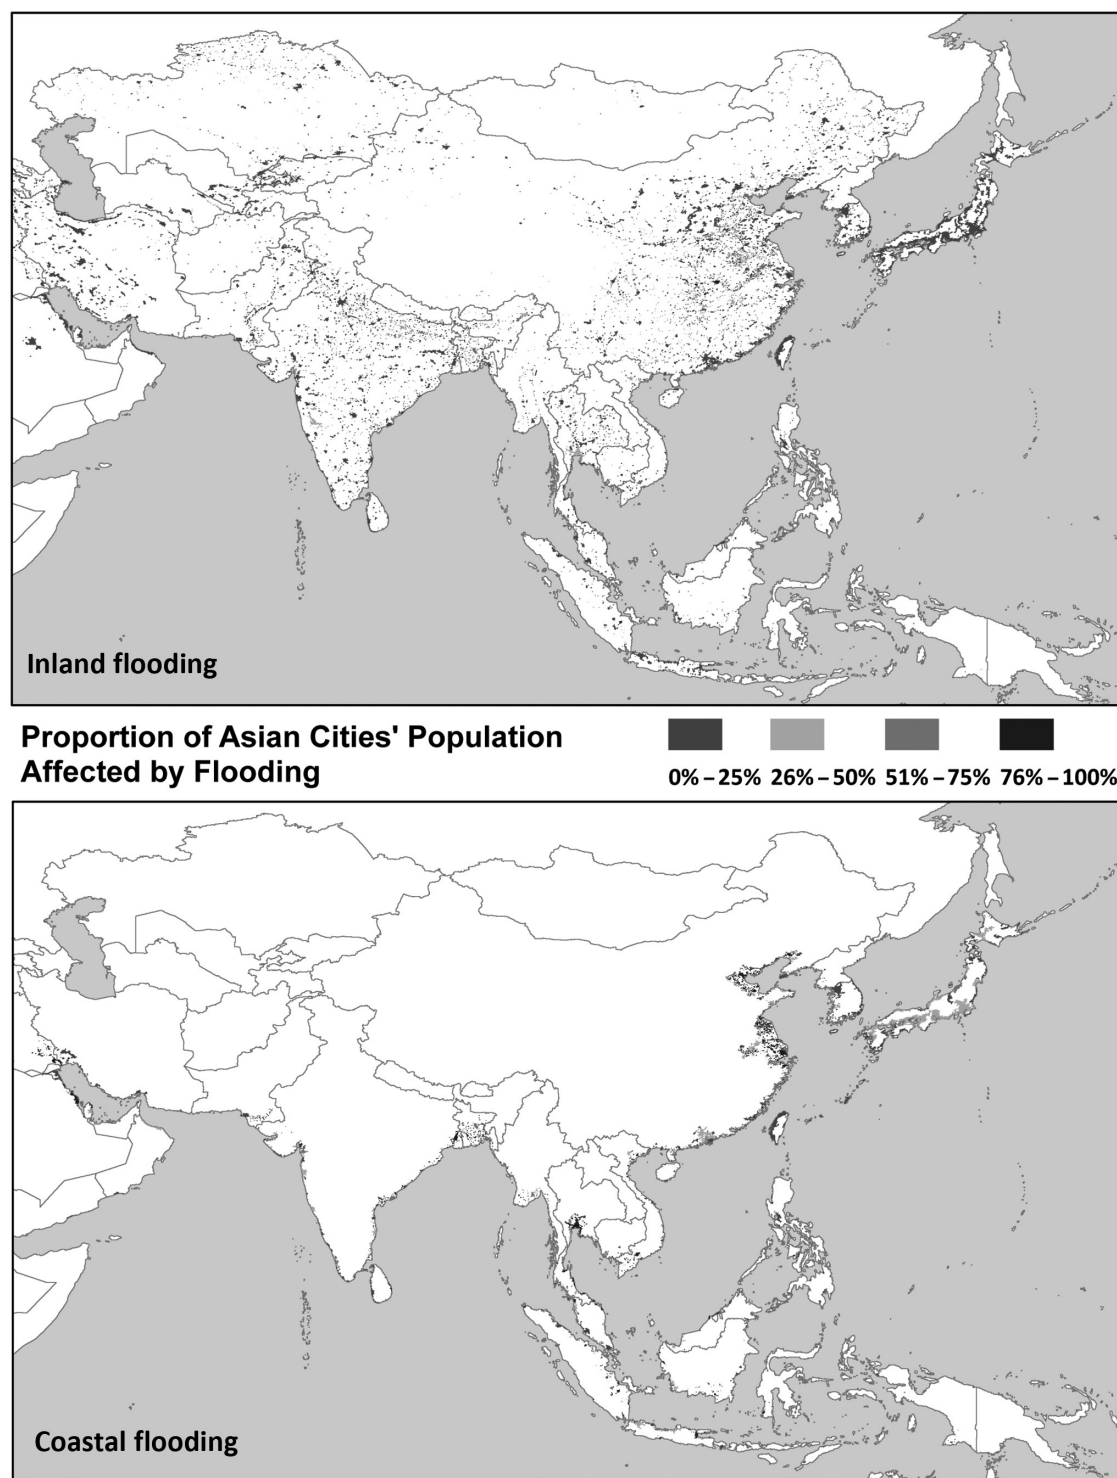

Fig. 9.7.6 For Asian cities, percentage of population at risk of coastal or inland flooding. Calculations by author with Deborah Balk and Zhen Liu.

factors: the predominance of impermeable surfaces that cause water run-off; the general scarcity of parks and other green spaces to absorb these flows; rudimentary drainage systems that are often clogged by waste and which in any case are quickly overloaded with water; and the ill-advised development of

marshlands and other natural buffers. When urban flooding takes place, faecal and other hazardous materials contaminate flood waters and spill into open wells, elevating the risks of water-borne disease. Urban floods are thus well-described as 'complex emergencies'. The urban poor are often more exposed

than others to these hazards, because the housing they can afford tends to be located in the riskier areas.

The international community is marshalling its response to such looming threats under the Hyogo Framework for Action (HFA) 2005–2015, an initiative which aims to fully integrate disaster planning, early warning, preparedness, and vulnerability reduction into economic development strategies, and which strives to ensure that multiple units and levels of government are well coordinated and linked with NGOs, community-based organizations, and other elements of civil society (International Strategy for Disaster Reduction 2009; United Nations 2007). While giving due consideration to needs for coordination at the international, regional, and national levels, the Hyogo Framework returns repeatedly to the theme of integration at the level of the community, as for example in the development of early warning systems that are people-centred, whose warnings are timely and intelligible to those at risk, and which tell people how and why they should respond to imminent threats (Red Cross/Red Crescent 2007; International Federation of Red Cross and Red Crescent Societies 2009). Urban adaptation strategies will need to be devised that are spatially specific and sensitive to the great variation across city neighbourhoods in the socioeconomic factors that determine exposure to risk, vulnerability, and recovery-resilience.

The risks posed by water scarcity are slower-developing, but arguably just as important to public health over the long term. As shown in Balk et al. (2009), nearly 1 billion city dwellers in poor countries live in arid zones, where they face shortfalls in drinking water on a seasonal or perennial basis that leave them with too little to meet basic daily needs. As global warming causes already-dry areas to become drier still, more city residents will be placed at risk. In the next two to three decades, however, the proximate cause of increases in exposure is not likely to be climate change as such, but rather the continued population growth of cities in arid zones. McDonald et al. (2011) examined the relative importance of demographic and climate change factors up to 2040, and found that over this period, population growth will be by some measure the dominant factor in increasing the numbers of people lacking adequate access to water.

Enough is already known to sketch the elements of an urban disaster risk reduction strategy for poor countries (Satterthwaite et al. 2007). But in moving from broad descriptions of such risks to focused, prioritized interventions, it is essential to document the specific cities and neighbourhoods that are repeatedly beset by excesses of water (that is, by flooding) as well as water insufficiencies. Internationally-accessible data repositories, the most prominent being the EM-DAT (<http://www.emdat.be>) database, record only the large-scale floods and droughts and do not pinpoint their locations. A promising alternative approach, which was pioneered in Latin America, is that of the DesInventar (<http://www.desinventar.net>) initiative. Its distinguishing feature is the effort to collect reliable information on a spatially specific basis for both small-scale and large-scale events. As more countries adopt this approach, an empirical record will accumulate that can help in setting intervention programmes on a firm grounding of evidence.

Local governments can be held politically accountable for their responses to local floods and similar disasters (Roberts 2008) and local political leaders would therefore seem to have a keen interest in addressing these risks. But in poor countries, and especially outside the largest cities and national capitals, municipal

governments are often severely constrained in terms of authority, budgets, and both technical and managerial expertise (Tanner et al. 2009; World Bank 2011; Jha et al. 2012). They are already overwhelmed with day-to-day management and generally lack the capacity to foresee and properly prepare for emergencies. If their needs have not been anticipated in the design of a decentralized system, smaller cities will likely face a yawning gulf between what they should do in the event of an emergency and what they are prepared for and able to do. To plan adequately for the upcoming era of climate change, the urban public health system must engage with partners across a broad range of urban agencies. Many of the priority areas needing attention are already areas of concern on other counts—for instance, improvements in water and sanitation systems for the urban poor—but the prospect of climate change adds a new element of urgency to them.

Conclusions

The sketch of urban health in low- and middle-income countries provided here is no substitute for the full treatment that the issues deserve, but it may at least suggest where further basic scientific and programme intervention research is most needed. A theme running through the discussion is the need for concerted action, with the public health sector working in tandem with other local government agencies. Public health professionals cannot by themselves mandate the provision of safe water and adequate sanitation for the urban poor, with all the attendant financial costs; nor can they, acting alone, rise to meet the challenges of mitigating urban air pollution, reorganizing traffic and pedestrian activities to reduce deaths and injuries, and readying cities to adapt to the threats that will be posed by climate change. What is needed is what Harpham (2007) terms ‘joined-up government,’ whereby public health agencies join with concerned actors in other sectors of municipal, regional, and national governments. Because the urban health system is dauntingly complex, with private for-profit and private non-profit care being a significant presence in most cities, effective partnerships are also likely to require engagement with the private sector. With political and administrative decentralization now well underway in many low- and middle-income countries, the arena in which creative partnerships are forged will increasingly be the local and municipal level. Much remains to be learned about how health expertise that is now situated in national ministries of health, and the international funding and technical assistance that has also been directed to national ministries, can be redeployed effectively to meet the many health needs of cities and their neighbourhoods.

The changing family

Gavin W. Jones

Family change across the world: kinship, family structure, and effect of socioeconomic and ideational change

The doyen of family sociologists, William Goode, argued that the differences between non-Western and Western family systems extended far back in time (Goode 1963, p. 22). Nevertheless, he went on to propose that there would in future be a convergence towards some form of nuclear, or conjugal, family system. In this, he was mistaken (McDonald 1992; Cherlin, 2009, p. 578). His key point that family systems in different regions have to be studied in their own right, however, holds: 'No useful analysis of African family systems can be undertaken using European concepts of marriage, household, parenthood, kinship' (Oppong 1992, p. 82). There is also no doubt that almost everywhere, family systems are changing in response to pervasive and far-reaching technological, socioeconomic and ideational forces. One of the best-known family sociologists in the United States recently wrote:

that the Western family 'changed more dramatically in the latter half of the twentieth century than in any comparable span of time in our history'. (Furstenberg 2011, p. 192)

Is the same generalization true for the rest of the world? Though conditions differ so greatly that it is difficult to generalize, Furstenberg's comment is certainly equally applicable to the East and South East Asian family, including China, and to the family in Latin America, though arguably not to the South Asian family.

What are some of the socioeconomic changes that have been impinging on family life? Firstly, the rapid pace of urbanization and rapid economic development in many parts of the world that were once characterized as 'less developed countries' has dramatically changed the options and the imperatives for family members. Latin America and East Asia are now heavily urbanized regions, and although urbanization is not as advanced in the rest of Asia or in Africa, even there some countries that were once predominantly rural, such as Indonesia, have passed the 50% urban population threshold. With more of the population drawn into the cities, and rising levels of education, particularly for women, the forces of globalization and neo-liberal economic structures have both drawn more women into the workforce and lessened job security. Then there have been remarkable technological developments in such fields as high-speed transportation, thus cutting travel times, and in social media, enabling a wider net of contacts to be maintained and providing instantaneous access to knowledge of all kinds. Technological developments in the medical field have widened the options in extending life and in avoiding

conception and birth, options which bring with them not only benefits but also a range of ethical issues.

In Asia, the world's most populous continent, trends in family change differ greatly between subregions and countries. Common elements in most cases are rising levels of female education and labour force participation, fertility decline, and a trend towards later age at childbearing (partly resulting from postponement of marriage), and rising rates of divorce. Both rising levels of education and economic (and advertising) pressures to maintain or increase consumption worked to propel women into the labour force. Ideological changes led to increased demands for equality in the workplace and in the home. Improved contraception has both loosened the tight connection between sexual gratification and marriage and enabled married women to postpone childbearing.

Family structures differ markedly between Asian countries, but it is possible to detect general patterns which differentiate South East Asia from the other main regions of Asia. Rigidly patrilineal kinship systems characterize northwest India, China and Korea, with patrilocal residence. In such systems, 'daughters were effectively lost to their parents when they married' (Das Gupta 2010, p. 128); women had no role as sister and daughter, but only as wife and mother. In the Indian system, there was resistance to enabling husbands and wives to be too emotionally attached, as this could threaten the unity of the patriarchal family (Caldwell et al. 1982). In contrast, the South East Asian region is characterized by bilateral kinship, which provides flexibility in post-marital residence, and continuing close relations between a woman and her natal family. In this region, there is a desire for children of both sexes; it is noteworthy that the only part of South East Asia that suffers from distorted sex ratios at birth due to misuse of pre-natal diagnostic techniques for non-medical purposes is northern Vietnam, which is the one area of South East Asia where most of the population does not follow a bilateral kinship system (Jones 2009, p. 13; Guilmoto 2012a). South East Asian kinship systems also facilitate the option of divorce if a marriage turns out unsatisfactorily.

These family systems have major health implications, for example, through the distribution of resources within and across generations. How resources are allocated depends on relationships of authority within families. Those in the family whose status is relatively low (typically based on sex, age, or birth order) tend to receive fewer resources. In societies where there is a strong preference for male children, infant mortality is higher among girls than boys (for India, see Das Gupta 1987; for Egypt, see Yount 2003; for China, see Coale and Banister 1994; Croll 2000), though in recent years the son preference has been manifested more in sex-selective

abortion, as a result of the ability to detect the sex of the fetus at an early stage (Guilmoto 2012b).

Accepted gender roles within families determine how much time women spend in the paid labour force as compared with childrearing and housework. There are complex implications for resource allocation and health. In Western countries, working women's greater earnings and increased status have given them more control over resources, but have probably contributed to increases in divorce rates and in rates of non-marital childbearing, both of which have resulted in increased poverty among women and children. Also, the dual responsibilities of market work and childrearing and housework responsibilities (see Hochschild and Machung 1989) can take a toll on women's physical and mental health, and potentially have adverse effects on other members of the family.

Smaller families

The size and composition of households is a dynamic process, changing over the life cycle as children are born, grow up, and leave the family. Migration affects household composition, as does the decreasing prevalence of extended family forms where these were once more prominent. Smaller nuclear, or conjugal, families do not necessarily mean fewer family relationships; as in many parts of the world, including Western countries, families tend to be 'residentially nuclear but functionally extended', in the words of a Filipino sociologist (Castillo 1979), and engage in 'intimacy at a distance'. The web of contacts, in other words, can be quite dense although members of the extended family may be living far apart, even in different countries. Revolutionary developments in communications have made such contacts easier to maintain.

Household composition, of course, is not the same as family composition. Solitary living has increased enormously in Western societies. Whereas in 1950, just 10 per cent of households in Europe were one-person households, five decades later, they accounted for 30 per cent of British and 40 per cent of Swedish households (Coontz 2004, p. 975). But solitary residence does not necessarily mean lack of family contact; nor are absent members necessarily uninvolved in family matters. Indeed, maintenance of the role of absent members—including those who live overseas for lengthy periods—both in household functioning and decision-making, is increasingly observed and accepted as part of the reality of a globalizing world with mobile populations (see, e.g. Parrenas 2008; Douglass 2011).

Whether we focus on the residential household or the family, however, the declines in fertility that have taken place almost universally except in parts of sub-Saharan Africa, clearly make for smaller family size. As measured by the total fertility rate (TFR)—the number of children a woman would bear by the end of her reproductive period if she followed the currently prevailing age specific fertility rates throughout her childbearing ages—fertility over the past three decades remained very low in Europe, declining from 1.9 to 1.6 children per woman; it declined from 2.6 to 1.6 in East Asia, from 4.5 to 2.2 in South East Asia, from 5.0 to 2.7 in South Asia, and from 4.2 to 2.2 in Latin America. Only in sub-Saharan Africa did fertility remain really high, still at about 5.0 children per woman in 2010. Fewer children being born into families directly lowers the number of family members living together, though more complex factors also affect family size. In

particular, different family types—whether nuclear or some kind of extended family, have different implications for family size. Nuclear families are the norm in Western countries and in a wider range of non-Western countries than was often recognized.

Average household size has been falling almost everywhere. For example, in Indonesia, average household size decreased from 4.87 people in 1971 to 4.27 in 1995 and 3.84 in 2010. In Thailand, it declined from 5.8 in 1970 to 4.6 in 1990, and was expected to continue falling steadily to 3.3 in 2015 (Mason et al. 1993, p. 70). Extended family contacts will, of course, widen the network of interaction, but not to anything like the extent in the past, when an average individual in Thailand had five siblings, six children, ten uncles and aunts, 30 nieces and nephews, 60 first cousins, 120 first cousins of his parents, and 720 second cousins.

When fertility falls to very low levels, there are fewer close relatives for an individual to interact with. An extreme example is the one-child family in China, resulting from a policy that requires over one-third of the population to have only one child, and over another half to have '1.5 children' (i.e. those whose first child is a girl can have a second child); in other words, more than 60 per cent of all Chinese couples are required to have only one child (Gu 2009, pp. 76–80). Where each family has only one child, that child has no siblings, and while he/she may have a number of uncles and aunts, because the parent generation was not yet subject to the one-child family rule, there will be very few cousins. Once the second generation of one-child families emerges, the web of close relatives shrinks further. If two only children, who are themselves the children of only children, marry, between them they will have eight grandparents (living or deceased) and four parents, but no cousins, aunts or uncles at all. Hence extended family relationships disappear in this context. Not only this, but the family responsibility to care for the elderly falls squarely on the young couple.

Many countries have even lower fertility rates than China. Where fertility has fallen to really low levels—TFR below 1.5—half of all women have at most one child (Le Bras 1979). This does not necessarily mean that most children are growing up as only children. For one thing, children are born to a cohort of women whose average number of children is currently higher than suggested by the cross-sectional snapshot provided by period fertility rates. But this aside, many women are not having children at all. The proportion of women not marrying before reaching the end of their reproductive period is now around 15 per cent in Singapore and Myanmar, well above 10 per cent in Japan and Thailand, and considerably higher than this for the tertiary educated in these and some other Asian countries. Having children outside of marriage is rare in these countries. Moreover, some of those who marry are not having children. In European countries, though having children outside of marriage is now common, an increasing proportion of adults are remaining childless; in Western Europe, around 10–20 per cent of the cohort of women born in 1965 remained childless at the end of their reproductive period. However, the situation appears rather different when viewed from the perspective of the child; no children, of course, grow up in no-children families. Among women who have children, many are having just one, but many are having two or more. Taking into account childless women, this can still average out at just above one per woman. As Preston (1976, p. 105) and Le Bras (1979) noted, women with large families contribute disproportionately to the average family size of children.

Comparing the families of five or six children typical of earlier generations and those averaging two children, there are significant differences in the way children are raised and the social dynamics within the family. Typically, in large families, the older children play a role from a young age in assisting with the raising of their younger siblings, and perhaps later in financing their education. With low fertility, parents' attention is focused on just one or two children. This has positive implications for human capital; the investment of money and time by the parents will no doubt assist their one or two children to achieve better results in school and in career-related activities. The trade-off between quantity and quality of children has been resoundingly resolved in favour of quality in the East Asian countries (Montgomery et al. 2000), in Western countries, and more recently in countries as varied in background as Brazil and Iran, and this is a major reason for the very low fertility they are now experiencing. The smaller cohorts of children should also enable government investment in education to achieve more per child.

What are the downsides to small family size? In China, both parents and the government fear the so-called 4–2–1 syndrome. This can be interpreted in two alternative ways: a great deal of attention focused on the one child by two parents and four grandparents, or as a weighty responsibility placed on the one child for the care of two parents and four grandparents as they age. When two only children marry, they will be responsible for four parents and eight grandparents. The young couple can only live with one set of parents, which means that the other half of their parent and grandparent families will be 'empty nesters'. What proportion of families are in this situation? It has certainly risen substantially, though exactly how much needs to be carefully studied. The issue is not unique to China. There are many single-child families throughout East Asia, despite the absence of a one-child policy, though in the other East Asian countries ultra-low fertility is due to a much larger extent than in China to non-marriage, and therefore to a larger proportion of potential couples with no children at all (Frejka et al. 2010, figures 4 and 5).

The issue of 'self-centredness' of only children is also frequently raised—the 'little emperor' syndrome. It is frequently speculated in China that divorce rates will rise with the clash of wills and personalities when two 'little emperors' marry each other. Inherently plausible as these speculations may be, they require evidence and research to back them up.

Delayed marriage and the rise of cohabitation

In Western countries, the 'golden age' of marriage from the 1950s to the 1970s (Festy 1980) has given way to an age of delayed marriage and increased cohabitation. Even though the rise of cohabitation has meant that delays in marriage do not accurately reflect the delay in forming relatively stable unions, overall, union formation and childbearing has been delayed (Mathews and Hamilton 2009). There are large differences between Western countries in the extent of the rise in cohabitation. Three broad groupings are evident. Cohabitation is very common in the Nordic countries, France, the United Kingdom, and the Netherlands (where among those aged 20–34 who are either married or cohabiting, 40 to over 50 per cent are cohabiting); there is an intermediate group of Germanic and Eastern European countries, the United States, and

Australia, where the proportion is around 20 to 30 per cent; and the Southern European countries and Poland, where cohabitation is less common (around 5 to 15 per cent) (OECD 2014).

The United States differs from the countries of Europe in significant ways in matters affecting cohabitation patterns; for example, Americans are more religious than other Westerners, though this religiosity is adapted to a culture of expressive individualism (Cherlin 2009, pp. 103–104, 113). Americans begin to have partners (whether married or cohabiting) at a relatively younger age than most Europeans, and to become parents at a younger age. Marriages and cohabiting relationships in the United States, and to some extent in Great Britain (Kiernan 2003, p. 32; Beaujouan and Ní Bhrolcháin 2011), are far more fragile than in most of Europe. American women are much more likely to spend time as lone parents in their teens or twenties than are women in Western Europe (Cherlin 2009, pp. 16–18). Overall, in the United States, about 41 per cent of births were non-marital in 2010—in other words being borne by single mothers or those in cohabiting relationships (Martin et al. 2012). The widening interval between sexual debut and marriage has exposed many more teenagers to the risk of pregnancy and childbirth outside marriage (Furstenberg 1990, p. 150), although the rate of teenage childbearing has declined considerably over the past decade.

In developing countries, very early marriage has long characterized most of sub-Saharan Africa and South Asia, as well as parts of South East Asia, the Caribbean, and Central America. In recent decades, average age at marriage has risen almost universally, but substantial proportions of women are still marrying very early. Comparable data from surveys conducted in the 1990–2001 period show that across the developing world, more than a third of women currently aged 20–24 had married prior to the age of 18 (Mensch et al. 2005, p. 137).

Unlike Western countries or Latin America, cohabitation does not feature importantly in Asian patterns of partnering. Asia does, however, show remarkable diversity in marriage systems and marriage patterns. While in general, average age at marriage is rising for both males and females throughout Asia, this rise is from a base that varies greatly. It is in East and South East Asia that truly remarkable changes in marriage patterns have taken place. In recent decades, the traditional universal marriage norms have been abandoned and the average age at marriage and proportions not marrying at all have risen sharply (Fig. 10.1.1; for more detail, see Jones 2007; Jones and Gubhaju 2012). However, there are wide differences between countries, and even between different ethnic groups within one country, such as Malays, Chinese, and Indians in Malaysia.

Broadly comparing East Asia, South East Asia, and South Asia, the changes in South East Asia as a whole are not as great as those in East Asia (excluding China), while most of South Asia remains firmly locked in an entirely different pattern of universal, arranged marriage. South Asian marriage systems have turned out to be remarkably enduring. While in East and South East Asia the location of most marriages on the continuum from parent-arranged to self-arranged marriage has shifted decisively towards the self-arranged end, very little such change has occurred in South Asia.

Socioeconomic change is undoubtedly responsible for much of the change in marriage patterns, but it is hard to explain the very high singlehood in Myanmar and the lack of change in Vietnam

Fig. 10.1.1 Proportion single among females aged 30–34, 1960–2010.

Source: data compiled by the author from population census reports for various years for the countries included.

in these terms. Within East Asia, Chinese marriage patterns differ widely from elsewhere; though average age at marriage for women is rising in China, marriage is ‘concertinaed’ at ages in the 20s, and by age 30, only a tiny proportion of Chinese women remain single. By contrast, in Japan, Korea, Thailand, Myanmar, Singapore, and among the Chinese population of Malaysia, delays in marriage have been such that substantial proportions of women remain single in their late 30s, an age beyond which not much childbearing takes place. Indonesia has seen gradually rising age at marriage but this has reversed according to the recent 2010 Population Census.

Turning attention to South Asia and South West Asia, The Islamic Republic of Iran shows a strong shift towards a delayed marriage pattern, with the proportion of women single at ages 35–39 not much below that in the Republic of Korea. However, in the Indian subcontinent, the lack of change in arranged marriage patterns in the face of very considerable socioeconomic change is striking. Evidence from a large survey in India (the India Human Development Survey 2005) indicates that:

Marriage decisions remain within the purview of the family, and less than 5% of the IHDS respondents had a primary role in choosing their husbands. However, nearly 62% of the respondents felt that they were consulted in this decision. (Desai and Andrist 2010, p. 675)

‘Consultation’ clearly did not go to the extent of arranging for the spouses-to-be to meet; among the respondents who felt they had a choice in partner selection, around 55% met their husbands on or around the day of the wedding. The persistence of early and arranged marriage in India is seen by Desai and Andrist (2010, p. 681) as ‘part of a script in which gender is performed by women through a symbolic display of segregation, modesty and chastity, and early marriage is part and parcel of culture in action’.

In Latin America, as in Europe, the key trend in union formation is the rise in cohabitation, which appears to have been just as marked as in Europe, though from a more complex starting

point. Latin America was marked by patterns of ‘old cohabitation’ (characterizing countries with mixed indio, mestizo, and European populations, and those with a history of slavery) and ‘new cohabitation’ (characterizing countries with more dominant European populations, notably Argentina, Chile, Brazil, Mexico, and Colombia). Cohabitation has increased sharply throughout Latin America in recent decades, though to varying degrees in different countries (Fussell and Palloni 2004; Esteve et al. 2012), and the long-standing educational gradient, whereby the better educated cohabited less and married more, has been attenuated. The factors lying behind these trends are complex, but ideational change in the direction of greater secularization and tolerance of non-conformist behaviour appears to be strongly implicated, except perhaps in Brazil (Esteve et al. 2012).

Late marriage, delayed transition to adulthood, and the role of singles

A trend affecting most of the world is the tendency for children to be dependants for a longer period of time, and to remain in the natal home until a later age. In agrarian and early industrial societies, children frequently began to work at quite a young age. Though age at marriage was young in many such societies, young marrieds frequently continued to live in the home of one or other set of parents until they had the resources to form their own household. The rise of universal schooling tended to delay both entry into the workforce and marriage, to a marked degree in countries where most children continue through secondary education and substantial proportions pursue tertiary education.

In the United States, 50 years ago, the vast majority of women and most men had completed schooling, left home, entered the workforce, and begun families of their own by the time they reached their early 20s (Furstenberg 2010). These transitions have now been considerably delayed (Arnett 2004). Likewise, in much

of Asia, extended education and delayed marriage are leading to later home leaving and in general a delay in reaching the milestones that signify adulthood and independence (Xenos et al. 2006). If adolescence is defined as the period between attaining sexual maturity and marriage, then it is a lengthening period in most young Asians' lives, though in South Asia, with the exception of Sri Lanka and to some extent Pakistan, early marriage remains the norm. In most of Asia, unlike in most Western countries (though the 'family-centric' Mediterranean countries share characteristics with Asian countries in this respect), there is a continued tradition of living at home until married, and in many countries, the need to do so is strongly reinforced by the high cost of owning or renting housing, and the convenience of living at home without paying board (on Japan, see Retherford and Ogawa 2006, pp. 17–19; on Singapore, see Jones 2012). Therefore, young people are living longer at home, in an unmarried state.

Many issues have to be negotiated between parents and children in this evolving situation. In East and South East Asian countries, only in the last few decades has extended singlehood become really common, so those who are remaining single into their 30s are a pioneering group, whose roles in family and society are still being negotiated (Situmorang 2007, 2011; Maeda 2008; Ibrahim and Hassan 2009; Tan 2010). Thailand, Singapore, and Myanmar are somewhat different in that over a fairly long period, substantial proportions of men and women have been remaining single, and this has led to adjustments of societal expectations, such that most singles do not feel much pressure to marry from family and friends. Little is known about the role of such singles beyond their immediate family, for example, whether working singles are contributing financially to education of cousins, nephews, and nieces.

In societies where girls were formerly married off on reaching puberty, or shortly thereafter, the transition to adulthood was abrupt and, for many, traumatic. This remains the case in much of Africa and South Asia. But elsewhere in Asia, delayed marriage has led to an extended period of adolescence between puberty and marriage, raising issues about sexuality and relationships with the opposite sex that simply did not arise in times of early, parent-arranged marriage (Lloyd et al. 2005). In Indonesia, for example, extended education for girls, long past the age at which their grandmothers were already married and having children, and widened employment opportunities, has brought them out of the household and into daily contact, not only with a range of men, but also with the stimulus of sexually explicit material through movies, videos, magazines, books, and the Internet. Premarital sexual activity is taken for granted in many of these information sources, but the material is designed to stimulate and titillate rather than to educate. Very little sex education is provided in schools or other contexts (Utomo and McDonald 2009, p. 137). At the same time, influences deriving from religion and ethnicity are still strong, and in some ways growing stronger. 'Faced with the conservative forces of idealized morality portrayed through religion, on the one hand, and Western influences promoting a more liberal approach on the other, it is little wonder that many teenagers are confused' (Jones 2002, p. 232).

There are other aspects of delayed marriage to keep in mind. One has to do with the maturity of the marriage partners. Five decades ago, when half of Malay girls in Malaysia were married before they reached age 17, they were unlikely to be emotionally mature at the time they married. But at least co-residence with

one or other set of parents—most commonly the bride's parents—meant a period of 'apprenticeship' into many aspects of married life. Age at marriage has now increased dramatically, and the age at which Malay women are bearing their first child is 4 years older than for their mother's generation and 7 years older than their grandmother's generation; some of them are having their first child in their mid to late 30s. There are a number of possible implications of later childbearing in both Asian and Western countries. Women are no doubt emotionally more mature when they are bearing their children, but they and their husbands may be more settled in 'child-free' ways, requiring a greater adjustment when the first child comes along than for couples who married at a younger age. The window of opportunity for having a second child is also very small when childbearing is postponed to these ages. Furthermore, there is a somewhat greater risk of birth abnormalities occurring when the mother and/or father are older. The greater availability of *in vitro* fertilization and assisted reproductive technologies enables more older mothers to have babies, but the risks of multiple pregnancies and premature births could contribute to chronic health problems in the children.

Divorce

In the second half of the twentieth century, divorce rates were on the whole higher in Western countries, particularly the United States and Russia, than in most of Asia (Dommaraju and Jones 2012, table 1). In South Asian countries, divorce is a rare event; divorce is not a feasible way out of a disharmonious marriage, because the options of returning to the natal family, or of earning an independent income, are not generally open to a divorced woman. However, the gap between Western and East Asian countries has narrowed because divorce rates stopped rising in many Western countries around the 1980s, while in East Asian countries, divorce rates have been rising steadily since 1980, particularly in the period since 1990 in the case of Japan, Republic of Korea, and Hong Kong. The rise in Republic of Korea was particularly sharp between 1995 and 2000—the period in which the Asian financial crisis occurred. In China, freeing up of divorce regulations in 2001 and 2003 may have contributed to the sharp rise in divorce rates in the 2000–2005 period. In Taiwan, as in other East Asian societies, increase in divorce has taken place in a context of decreased prevalence of marriage. The chance of re-marriage after divorce has declined (Yang and Tsai 2009), indicating a growing acceptance of and perhaps preference for singlehood.

Japanese divorce rates have risen to such an extent that Japan can no longer be considered as a society characterized by low levels of marital dissolution. About one-third of Japanese marriages are now likely to end in divorce (Raymo et al. 2004). Traditional marriage stability in Japan, while it did not necessarily have much to do with whether a marriage was happy, at least gave some assurance that children would be cared for, and that wives could expect economic security. With the awareness of increasing fragility of marriage, decisions about whether to marry and about whether to raise children when single motherhood is a possibility, come more into play (Bumpass et al. 2009, p. 223).

Trends in divorce in East Asia appear, then, to be going the way of the West, and partly for the same reasons (Dommaraju and Jones 2012). Substantial increases in divorce rates in East Asian countries signify a significant change in circumstances and attitudes to

divorce, because in the past divorce carried a considerable stigma, and the pressure to remain in a disharmonious marriage for 'the sake of the children' and also for the sake of appearances and family honour, was very strong. It would appear that factors such as increasing economic independence of women, and the pressures (and widened range of personal contacts) in the big city environments in which an increasing proportion of East Asians live, are influencing divorce trends.

In Western countries, divorce rates no longer reflect very accurately trends in the breakdown of long-term relationships, because of the rise of cohabitation. It is impossible for couples who are not officially married to divorce. Understanding the relationship of cohabitation to breakdown of unions requires analysis of the proportion of cohabiting relationships that are dissolved; the proportion that are converted to marriages; and the proportion of such marriages that are dissolved. In Europe, around one-third of cohabiting unions are dissolved within 5 years (Kiernan 2003, table 1), considerably higher than the proportion of marriages that are dissolved within the same length of time; of cohabiting relationships that are converted to marriages, divorce rates also tend to be higher than for marriages that did not commence with a cohabiting relationship, though 'when the pre-existing characteristics of those who cohabit are taken into account, the risk of marriage breakdown is no different from and may be lower among those cohabiting before marriage than among those who marry directly' (Beaujouan and Ní Bhrolcháin 2011, p. 19). In any case, official figures on divorce trends clearly do not fully reflect the breakdown of long-term relationships, many of which, both marital and cohabiting relationships, involve children. It might be noted that in Japan, while divorce rates do not fully reflect relationship breakdown because cohabitation is increasing, the breakdown of cohabiting relationships rarely involves children, because very few children are born to cohabiting couples.

Non-marital childbearing, divorce, and effects on children

In Europe, 'sexual activity, childbearing and marriage have become disconnected so that increasingly it is socially acceptable to have one without either of the other two. But this has happened in different ways in different parts of Europe' (Pritchett and Viarengo 2012, p. 67). Notably, in northwest Europe, childbearing remains reasonably robust, much of it in non-marital relationships; in many countries of Eastern and southern Europe, though, marriage rates remain high and extramarital births are rare but fertility is very low.

Changing conventions about marriage and divorce in the West and in East Asian countries have multiple causes. In the West, 'family relations have become more discretionary; a greater premium is placed on emotional gratification and a lower value on obligation and authority' (Furstenberg 1990, p. 153). Such factors, stressed in 'second demographic transition' theory (van de Kaa 1987; Lesthaeghe 2010), have explanatory power for Western countries and perhaps for Japan; for East Asia more generally, however, more important than individualism may be women's willingness to break from the shackles of patriarchal structures in a context of widened economic opportunities. Moreover, some weakening in these countries of community perceptions of divorce as a

disgraceful event has undoubtedly lowered the bar to the decision to divorce.

In all these contexts, however, the effect of divorce on children needs to be considered. As Carlson and England (2011, p. 2) put it: 'The freedom to leave unhappy relationships might be counted as a victory for adults, but the same cannot be said for children'. Multiple studies suggest that children whose parents divorce have a greater risk during late childhood and early adolescence of experiencing 'school failure, delinquency, precocious sexual behavior, and substance abuse' (Furstenberg 1990, pp. 161–162). Nevertheless, the effect of divorce on children is a complex subject. Many studies suffer from methodological shortcomings, and assessments differ, particularly with regard to whether family conflict produces more adverse effects on children than divorce itself (Cherlin 2009, pp. 19–24, 192–197).

The effect of marital disruption (and more generally, in the era of cohabitation, relationship disruption) on children is a controversial and emotional issue. Many studies show that children raised by solo mothers or by a mother in unstable relationships are more likely to experience emotional and behavioural problems than children growing up in stable married families. For example, in Britain, 'children born into cohabiting families where the parents had separated and solo mothers who had not married the natural father. ... were around three times more likely than children in stable married families to be exhibiting behavioural problems' (Kiernan and Mensah 2009). However, careful control for factors lying behind the differences in the family situation in which children grow up is necessary before attributing the behaviour to the family situation itself. In the British study under discussion, controls for various factors—notably the mental well-being of mothers and family poverty—attenuated the differences, though they did not eliminate them entirely (Kiernan and Mensah 2009). On the other hand, when the child's emotional well-being was the dependent variable, it appeared that the parental socioeconomic circumstance and mother's mental well-being may fully account for differences between children living in different family trajectories.

In sub-Saharan Africa, patterns whereby many fathers do not continue to live with their children are common (Adepoju and Mbugua 1997; Therborn 2004, pp. 177–181). In parts of Africa characterized by polygyny, the mother–son bond tends to be strong. In South Africa, among the African population, in 2007 only 29 per cent of children aged 17 years or younger were living with both parents, while 43 per cent were living with mother only, and 26 per cent were living with neither parent (Republic of South Africa 2012, table 2.6). Almost half of children whose father was alive had no contact with him; unfortunately, in South Africa, 'family instability in childhood plays a major role in setting young people on pathways to adulthood that potentially compromise their life chances' (Goldberg 2013, p. 246).

Ageing and the family

The trend towards an older population is an inexorable one in most parts of the world. Japan has the oldest age structure of any country in the world (23 per cent of the population aged 65+), followed by Europe as a whole (16 per cent). Some Asian countries—Republic of Korea, China, Singapore, and Thailand—are well along in the ageing process, with between 8 per cent and 11 per

cent elderly. But many of the higher-fertility countries in South Asia and Africa have only around 3 or 4 per cent in the over-65 age groups. Everywhere, however, the percentage of elderly is rising, and by 2030 it is expected to reach 30 per cent in Japan, 22 per cent in Europe, and 17 per cent in China and Thailand.

There is little doubt that issues related to population ageing will be central, not only to national policy reactions to ultra-low fertility, but also to family level adjustments needed to cope with radically altered population structures. At an aggregate level, the issues can be well illustrated by trends in ageing support ratios—that is, the ratio of the population aged 20–64 to the population aged 65+. Admittedly, the age limits used for this calculation do not accurately reflect the actual dependency situation, which depends on the ages at which people actually enter and withdraw from the labour force, and on the proportion of the elderly requiring various kinds of support (in the case of physical support, usually quite small). But as a general indicator, the ageing support ratio does give a sense of the trends which are so dramatic that modification of these ages will not alter the picture greatly.

The ageing support ratios were vastly different in different world regions in 1980 (see Fig. 10.1.2). Since then, they have fallen sharply in East Asia and South America, and this sharp decline is expected to continue until 2050. South Asia is 35 years behind East Asia in reaching an ageing support ratio as low as 8. In the 40 years between 2010 and 2050, the ageing support ratio will halve in Japan, and will fall to less than one-third its current level in countries such as China, Thailand, and Brazil. Leaving aside Africa, where the decline in the ageing support ratio will be very

slow, and South Asia, where it will be relatively slow, there will be a marked convergence in ageing support ratios in the different regions at very low levels—around 2 to 3. Such declines will require major adjustments of policies with regard to income support programmes, orientation of health services to give much more weight to gerontology, and labour market policy, including retirement ages.

It should be noted that living arrangements of the elderly differ considerably in Asia from those in Western countries, with a much higher proportion living with a child or grandchild (United Nations 2005). And although the percentage of elderly Japanese and Koreans living with a child or grandchild has been gradually declining, it does not appear likely to reach levels as low as in France or the United States. Demographic trends do, however, raise issues about whether the family can be relied on as in the past to provide care for those elderly who need it. There are a number of aspects to the problem. The first is the sharply declining ratio of potential carers to numbers of elderly, as crudely indicated by trends in the support ratios. The number of living children of older persons has been declining through movement of smaller birth cohorts into the main ‘caring ages’. And as documented by Schroder-Butterfill and Kreager (2005) in a study in East Java, *de facto* childlessness may differentially affect the poorest and most vulnerable groups. The second is that a high proportion of the potential carers (usually women) are now drawn into the paid workforce (consistent with government policy in these countries), and are therefore not available for full-time caring work. Moreover, many of these potential carers are in the so-called

Fig. 10.1.2 Ageing support ratios (population aged 20–64/65+) by region.

Source: data from the detailed indicators in United Nations Population Division, *World Population Prospects: The 2012 Revision*, Copyright © 2014 United Nations, available from http://esa.un.org/unpd/wpp/unpp/panel_indicators.htm.

sandwich generation, required to support not only the grandparent generation but also their own children who are spending a longer time living with (and depending on) their parents. The third is that, despite the general improvement in health status of the elderly at any given age, the rising proportion of the elderly and the rising proportion of the elderly who are 'old-old' (i.e. 75 years and above) will inevitably mean a rising load of frail and disabled elderly, who need full-time care. The ratio of elderly population who suffer from senile dementia to non-working women at various ages is projected to rise substantially over the coming two decades in Japan (Ogawa 2006, figure 11). This suggests that Japan will not be able to rely on the traditional family support network to care for the infirm elderly; the rise in the burden placed on middle-aged Japanese women providing in-home nursing care will simply be too great.

There will be less possibility of the family providing intensive care for the increasing number of disabled or frail elderly in Asian countries, for three reasons: the lowered proportion of children per elderly person, the increased labour force participation of women (the traditional carers), and the movement of children of the elderly to other localities. These trends have major implications for policy on elder care. Despite the tradition in Asian families of caring for family members in various kinds of need, and official rhetoric about the key support role of the Asian family as a fundamental (and by implication, unchanging) characteristic of Asian societies, this traditional reliance on family will be subjected to intensive pressures. Governments will almost inevitably be forced to step in.

We need to bear in mind that co-residence is not the only indicator of close caring relationships. Assistance can notionally be divided into three categories: financial assistance, emotional support, and physical support. The first two of these do not require co-residence, particularly in the age of the mobile phone. In Thailand, there has been an extraordinary rise in the proportion of the elderly living in houses with a telephone—from 15 per cent in 1994 to 76 per cent in 2007. Moreover, while the proportion of elderly living in the same house as a child is slowly declining in Thailand, the proportion is considerably higher if those living in close proximity are included (Knodel and Chayovan 2008, p. 41).

The care needs of the elderly should not be exaggerated. The great majority of the elderly do not need care; for example, in Thailand, more than 80 per cent of those in their 70s and even 65 per cent of those aged over 80, say that they can care for themselves (Knodel and Chayovan 2011, table 1). The positive contributions made by the elderly in society and family, for example through taking care of grandchildren and through serving as mentors and confidants of their grandchildren as they enter adolescence, need to be recognized and supported (Hamid and Yahaya 2008; Ananta and Ariffin 2009).

The challenge, of course, in harnessing the capacities of grandparents to develop a special relationship with their grandchildren, is to avoid burdening them with what are sometimes exploitative child-minding arrangements. In all societies, the role of grandparents in childcare appears to be greatly valued, as opposed to the alternatives of formal childcare arrangements or, in some countries, reliance on domestic servants. 'Grandparent care is commonly viewed as the "next best thing" to parental care, and is highly valued for its supposed intrinsic benefits: the fostering of

closer inter-generational relationships, the quality of grandparent care in contrast with the formal market, and the satisfaction that grandparents apparently derive from the caregiving role' (Jenkins 2010, p. 6; see also Wheelock and Jones 2002). However, grandparents are not always so positive about the role, which can be very stressful, especially when they feel that they lack the choice to determine the parameters of their caregiving.

The family, development, and health

Being born into the wrong family can almost guarantee a difficult life. 'The family has long been a mechanism by which advantage—and disadvantage—is transferred across generations' (Carlson and England 2011, p. 9). In the American context, Lareau and Cox argue that class differences in parents' cultural resources (e.g. knowledge necessary to help their children interact with institutions—such as gaining access to college-prep courses in high school and navigating the college admission process) serve to exacerbate inequality in the life chances of youth from different classes, especially in getting a college education (see Carlson and England 2011, p. 14). In Indonesia, only 2 per cent of the children of the poorest 20 per cent of the population continue to tertiary education, compared with 40 per cent of children of the richest 20 per cent.

From a public health perspective, issues abound in relation to conventional family structures as well as to rapid changes in these structures. Many examples could be given, but one will be chosen here: reproductive health issues arising from two contrasting situations—patterns of early marriage and childbearing in Africa and South Asia, and delays in marriage in other developing countries.

In many sub-Saharan African countries, as well as in Bangladesh and parts of India, data from the 1980s and 1990s showed that more than 10 per cent of women in their early 20s had had a child by age 15, and between a quarter and a half had a child by age 18 (Singh 1998, table 2). In conditions of high mortality, 'socialization processes that support and encourage early marriage and childbearing are often deeply entrenched' (Singh 1998, p. 133), and these socialization processes do not change rapidly in the face of declining mortality. The dangers of early childbearing to the health of mother and child are well known. But other dangers emerge when marriage is delayed and young people are exposed to the risks of premarital intercourse for longer periods of time: a greater risk of unintended pregnancies, induced abortion and sexually transmitted diseases. Increased levels of infection by sexually transmitted diseases and HIV can affect young women's health and indeed survival, the outcome of their pregnancies, as well as their future fertility. Yet policies in many countries make it difficult for the unmarried to obtain access to contraception.

The family is seen in most countries as the key institution on which a stable society is built. Thus changes in family form and function are normally suspected of threatening the social order. One concern tends to be about ageing, and whether the family will continue to have the capacity to provide the necessary physical, social, and emotional support for the elderly as their share of the population increases. Delayed marriage also leads to disquiet, though not, in most countries, to specific policies to encourage marriage. But it raises important issues about the role of singles in

society, as well as practical issues such as their access to contraception, which proves to be divisive in many countries.

Family policy in many countries tends to be conservative in promoting the generally accepted family values. The model of universal heterosexual marriage in which children are raised in an intact family until they marry and leave home is the norm. In Asian countries, this of course remains overwhelmingly the main family form, and there is a great deal to be done to enhance the quality of life for mainstream families of this kind. One key need is to develop policies that will facilitate marriage and enable women and men to combine work with childrearing—to avoid the low fertility trap that East Asian countries have perhaps entered into, but also to enable women to realize the potential resulting from their higher levels of education, without succumbing to the exhaustion of the ‘double shift’. At the same time, in countries such as India, Bangladesh, and Indonesia, stricter enforcement of legal minimum ages at marriage is needed, to lower the proportion of girls being married below this age.

But there are also other family forms in all societies, including childless couples, those cohabiting without entering formal marriage, blended families following re-marriage, the various kinds of lesbian/gay/bisexual/transgender (LGBT) pairings (Blasius 2001), single parents post divorce raising a child or children, and singles continuing to live with parents until into their 30s. The reality of considerable pluralism in family types and functions needs to be recognized. It is important that those who are not in mainstream family relationships are not made to feel ostracized and discriminated against by policy.

On elder care, increased strain will be placed on families whose characteristics and circumstances are changing in ways that will make it increasingly harder to deal with these strains. For example, in India, the percentage of elderly people is expected to double in 27 years after 2010, to 10.5 per cent. In Thailand, this percentage is expected to increase by 2.5 times over the same period, to 20.5 per cent. Although the percentage of elderly in India in 2037 will be only half that in Thailand and only a third that in Japan, even the smaller increase that India faces poses significant challenges. The policy emphasis in all countries must be on active ageing, financial independence, and a positive attitude towards the contribution the elderly make within families. Nonetheless, an increasing role of government in elder care cannot be avoided. The retirement age in many countries also needs to be increased, as it reflects the life expectancy situation decades ago, and will be increasingly untenable in terms of providing income maintenance for the rapidly increasing number of retirees. The extent to which government needs to replace the role of family in elder care, and its capability of doing so, will vary across regions.

Women, men, and health

Sarah Payne and Lesley Doyal

Women, men, and health: an introduction

This chapter focuses on sex and gender influences on the health of men and women. In recent decades health professionals and policymakers have taken an increased interest in the ways in which the risks of early mortality, and the causes of death and poor health, vary for men and women. At the same time research in the medical and social sciences has helped to identify more closely the significance of sex and gender influences on health and also the complexity of such influences.

Although we focus here specifically on sex and gender, it is important to note from the outset that differences between women and men across the life course need to be seen in the context of other influences. Socioeconomic status, ethnicity, age, and sexuality are especially important although more research is needed on the nature of these intersectional influences on health (Iyer et al. 2008). In addition the health gap between women and men varies globally, reflecting levels of development within countries, cultural influences, and health system factors including access to care.

In the following sections we explore some of the explanations for these differences between women and men in their experiences of health and healthcare and their likelihood of developing specific diseases. We begin with an overview of data on male and female mortality and morbidity, before looking at the part played by sex and gender in shaping these variations. The picture which emerges from this exploration suggests quite complex factors are involved and various directions of causality. The next section will therefore look in more detail at the ways in which sex and gender, alongside other determinants of health such as geographical location, poverty, and socioeconomic status, can influence health. This will be done through examining specific conditions, including coronary heart disease (CHD) and HIV/AIDS. We finish this chapter with a discussion of gender differences in the appropriateness and availability of healthcare.

Men, women, and mortality

Mortality data are widely available on a global basis, are relatively reliable compared with some other measurements of health, and begin to suggest how health differs between women and men—although of course mortality is inevitably a very crude measurement of absence of health. Figures for life expectancy at birth show that women can expect to live longer than their male counterparts in virtually every country (see Table 10.2.1). In 2009, for example, there were only three countries worldwide where men might

expect to outlive women: Tonga, Tuvalu, and the Central African Republic (World Health Organization (WHO) 2012a). There were three further countries where men and women had the same life expectancy, while in the remaining 187 countries women could expect to live longer than men.

Many of the countries with a narrow gap between women and men have low levels of life expectancy overall, particularly those in the sub-Saharan region of Africa. For example, in Nigeria, women had only 1 year's advantage over men, while in Sierra Leone, women's life expectancy was 2 years higher than that of men (WHO 2009). These low levels of life expectancy reflect a number of social determinants of health, in particular poverty, poor nutrition, and weak health systems, while for women they also reflect rates high maternal mortality.

The countries where the mortality gap between women and men is narrow also include some with higher average life expectancy. For example, women have only a 2-year advantage over men in Bangladesh and in Pakistan, where life expectancy is in the low 60s, and only a 3-year advantage in Algeria, where overall life expectancy is 72 (WHO 2009).

Where there is a wide gap between women and men, overall life expectancy is higher, although these countries are diverse in terms of economic status, level of development, and culture: Brazil, Malawi, France, and Kyrgyzstan, for example, all have a female advantage of 7 years (WHO 2012a). Countries in Eastern Europe have some of the greatest advantages in female life expectancy. Seven countries with a gap between female and male life expectancy of 10 years or more were formed following the breakup of the USSR, including the Russian Federation where in 2009 the female advantage was 12 years, reflecting a deterioration in men's health prior to the dissolution of the USSR which was followed by further increases in male mortality during social changes experienced in the post-communist era (Pietilä and Rytönen 2008). One of the most important features of life expectancy, in recent years, has been a trend in richer countries towards a narrowing gap between women and men, reflecting primarily improvements in male health (Organisation for Economic Cooperation and Development (OECD) 2011).

These variations in the gap in life expectancy between women and men across different cultures, time periods, locations, and levels of development indicate that the underlying reasons for such differences do not simply reflect economic factors or specific cultural factors but are explained by quite complex influences involving both biological and social causes, as we shall see.

Mortality can also be explored across the life course, revealing further patterns of difference between males and females.

Table 10.2.1 Differences in male and female life expectancy, 2009—selected countries

Country	Male life expectancy at birth 2009	Female life expectancy at birth 2009	Difference in years (negative = female advantage)	Difference in years in 2004
Russian Federation	62	74	–12	–13
Sri Lanka	65	76	–11	–7
Estonia	70	80	–10	–12
Cambodia	57	65	–8	–7
Republic of Korea	77	83	–6	–8
Finland	77	83	–6	–7
Czech Republic	74	80	–6	–6
United States of America	76	81	–5	–5
Australia	80	84	–4	–5
United Kingdom	78	82	–4	–5
China	72	76	–4	–4
Egypt	69	73	–4	–4
Samoa	68	72	–4	–4
Nepal	65	69	–4	0
Kenya	58	62	–4	+1
Côte D'Ivoire	49	52	–3	–6
Iceland	80	83	–3	–4
India	63	66	–3	–2
Angola	51	53	–2	–4
Sierra Leone	48	50	–2	–3
Pakistan	62	64	–2	–1
South Africa	54	55	–1	–2
Niger	57	58	–1	+1
Somalia	51	51	0	–2
Cameroon	51	51	0	–1

In 2011, for example, there were only two countries where girls under 5 years had a higher mortality risk than boys: India and the Solomon Islands (WHO 2012d). In 14 countries, under-5 mortality rates were the same for both, including Bahrain and Sweden, while in the majority of countries, boys under the age of 5 die more frequently than girls. The greatest excess risks for boys are found in sub-Saharan Africa: the under-5 mortality rate for boys is around 174 per 1000 live births in Guinea Bissau compared with a rate of 147 for girls (WHO 2012d). Thinking through the explanations for this range of differences in under-5 mortality rates starts to open up the way in which both sex and gender impact on health chances. The variations in how many girls and boys die before their fifth birthday reflect biological influences, alongside social, economic, and cultural factors, including gender differences which affect the treatment of girl and boy children (Ravindran 2000).

There are also differences in life expectancy at the other end of the life course, although the gap between women and men is often less extreme. For example, although there is a 12-year female

advantage in overall life expectancy in Russia, by the age of 65 this advantage has narrowed to 5 years, and is only slightly higher than other countries including Japan, France, and South Africa (OECD 2011; United Nations (UN) 2012).

There are further variations between women and men in what they die from, and again exploring these helps to illustrate the importance of both sex and gender in health chances. Globally, similar proportions of men and women (26 per cent and 29 per cent) die from communicable diseases such as respiratory infections, tuberculosis, or HIV and AIDS (WHO 2011a). A further 62 per cent of men and 65 per cent of women die from non-communicable diseases. However, there are wider differences between men and women in accidental and non-accidental injury, which accounts for twice as many male as female deaths (WHO 2011a). Within this category, men are more likely than women to die as a result of homicide, particularly among younger age groups, with four times as many deaths among men from violence (WHO 2012f). There are also gender differences in the

perpetrators of such violence: women are more at risk of being killed by close family, particularly partners, while more men are killed by people outside their circle of family and acquaintances (Hemmenway et al. 2002).

Men are similarly much more likely than women to die or be injured as a result of conflict, and more than 90 per cent of deaths in conflict situations are among men (WHO 2011a). This reflects the ratio of men to women both in formal military organizations and in informal or paramilitary organizations, as well as the roles played by men and women in such organizations. However, conflict situations also increase the risk of poor health for women, including, for example, infectious diseases, accidental death, and sexual violence (WHO and London School of Hygiene and Tropical Medicine (LSHTM) 2010). In addition, displacement among civilian populations due to conflict combined with the loss of employment, land, or source of income creates economic insecurity and poverty, leading to high risks of poor mental health and malnutrition among displaced populations, the majority of whom are female.

There are also differences between men and women in other injury-related deaths. For example, in Mauritius the male road traffic mortality rate is six times greater than the female rate, while in Egypt and the United States, male mortality is twice as high as female road accident mortality (WHO 2011a).

One important cause of female deaths in many countries is maternal mortality. Although this accounts for less than 1 per cent of all female deaths worldwide (WHO 2011a), it is a particularly modifiable cause of death, in that improved healthcare before conception, during pregnancy, and in childbirth can dramatically reduce the risk of death. As such, maternal mortality is also important in explanations of the ways in which the ratio of male:female deaths varies over time and between countries.

More than 280,000 women died in 2010 as a result of complications following pregnancy and childbirth, including problems arising from miscarriage and terminations, and deaths due to women's reduced immunity to some diseases during pregnancy or deterioration in a pre-existing illness as a result of pregnancy or childbirth (WHO 2012f). The risk of maternal mortality varies widely: the majority of deaths occur in less economically developed countries and there has been a significant decline in the number of maternal deaths worldwide in recent years (WHO 2012f). However, the decrease is less than is needed to meet the Millennium Development Goal on maternal mortality, and in some countries rates have increased. For example, the maternal mortality ratio in Chad in 2010 was 1100 maternal deaths per 100,000 live births (up from 920 in 1990) and in Somalia the rate was 1000 per 100,00 live births (an increase from 890 in 1990) (WHO 2012f). These rates compare with very low ones in high-income countries such as Australia, where the rate was 7 per 100,000 live births, and Sweden where the maternal mortality rate was 4.

Variations in the relative risk of dying as a result of pregnancy and childbirth reflect the importance of social determinants of health, particularly poverty, nutrition, the availability of care, as well as maternal age and number of previous pregnancies. In Sierra Leone, for example, three-fifths of births are not attended by skilled health personnel. Similarly, in Niger, a country with a maternal mortality rate of 1600 per 100,000 live births in 2000,

only 11 per cent of women received skilled healthcare during childbirth (WHO 2012f).

Overall, then, women have longer life expectancy than men, although the gap varies between countries and there are differences between women and men for some causes of death. The next section explores alternative indicators of the differences between women and men, focusing on measures of morbidity or illness.

Men, women, and morbidity

Figures for death are useful for broad comparisons between women and men but they also have limitations. Most importantly, they do not accurately capture health experience across the life course. Some causes of death are not usually associated with a period of ill health beforehand—accidental injury, for example—while others may be associated with poor health and low quality of life for some years before death occurs. And of course there are many illnesses which are serious and debilitating but not life-threatening. This is important when exploring health differences between women and men as it is possible that excess male mortality does not equate to a similar disadvantage in terms of health enjoyed during a lifetime.

In the past some writers argued that despite their advantage in life expectancy, women experience poorer health during their lives in comparison with men—the suggestion that ‘women get sicker but men die quicker’ (Lorber 1997). However, growing evidence on patterns of health across the life course reveal a more complex reality. The gap between women and men widens or narrows at different stages reflecting different age-related patterns of health (Payne 2006). In addition more women are diagnosed with some illnesses—osteoarthritis, for example—while men are more at risk of others, including respiratory diseases (Zandman-Goddard et al. 2012).

One of the reasons why there is no simple story to tell in terms of the burden of ill health among women and men is that morbidity can be measured in a range of ways, and each measure is potentially different in terms of how well it captures the experiences of men and women. The main indicators include self-reported health, based on individuals' judgements of their own health; data on use of healthcare services, including inpatient and community services; and composite indicators of health at population level, such as measures of healthy-adjusted life expectancy (HALE) and measures of disability-adjusted life years (DALYs). Each of these shows a range of differences between women and men which vary across the life course as well as between different demographic groups and between countries.

Self-reported health

There are variations between countries in whether women or men are more likely to report their health as poor. The WHO's *World Health Survey* from 2005, for example, showed that in China, France, India, Malawi, Pakistan, and Portugal more women reported their health as either bad or very bad, while more men reported their health as either good or very good (WHO 2005).

The size of the gap between women and men varied in this survey, with particularly wide differences in the Russian Federation where nearly a quarter of women reported their health as either bad or very bad, compared with 13 per cent of men (WHO 2005)—a finding which contrasts to the much higher mortality

among men and highlights the complexity of these measurements and what they mean.

More recent figures (OECD 2011) reveal greater proportions of men who report their health as good or excellent, compared with women, across a range of different countries, including Denmark, France, Poland, and Japan. The gap between women and men is similar despite country-level variations in levels of health overall. For example, in France, 71 per cent of men compared with 66 per cent of women described their health as good or excellent, and while overall levels of good health were much lower in Japan, a similar difference exists between men and women with 31 per cent of men and 28 per cent of women reporting their health as good or excellent.

However, women do not always report poorer health than men. In the OECD data more women (70 per cent) than men (66 per cent) reported their health as good or excellent in Finland in 2011 (OECD 2011). In Australia, national data for 2011–2012 showed that similar proportions of women and men reported their health as either very good or excellent (Australian Bureau of Statistics 2012). Recent data from both the United States and England also reveals little difference between women and men in how they report their health status (Craig and Mindell 2012; Sondik et al. 2012). The range of variations between countries is difficult to interpret. They might reflect variations in the wording of survey questions and some are also influenced by whether or not the data are age-standardized. They might also reflect class or income differences as poorer health is reported by those in lower-income groups, which may include a greater proportion of women in some countries, especially less affluent ones (World Bank 2012). As these differences are based on a subjective measure it is likely that cultural differences are also important in shaping perceptions of health status.

However, the variations, particularly the relatively narrow gap between women and men in richer countries compared with the wider gap found in poorer countries, might also reflect the fact that men in some societies do enjoy better health than women.

One indication of the limitations of self-reported measures comes from studies showing that men who report poor health are more likely to die prematurely than those reporting themselves as being in good health. However, there is less evidence of such an association for women (Benamins et al. 2004; Jylhä 2009). This may mean that self-report surveys are measuring different things for women and men. One factor that affects self-reported health is the extent to which there are gender differences in knowledge about how some behaviours affect health risks, including smoking and diet, for example, and in how this knowledge is drawn upon in self-assessments of current health status.

Use of health services

Health differences between women and men can also be explored using data on consultation with health professionals. Again these figures are likely to be influenced by more than health status and symptoms alone. A number of considerations affect the use of healthcare, including: economic factors such as whether an individual has health insurance or the means to pay user fees in countries where access to healthcare requires payment; the ability to take time off from either paid employment or caring responsibilities to visit health facilities; and the availability of appropriate services and transport to reach them.

Of course these factors are themselves influenced by gender. For example, women are more often responsible for the care of children and vulnerable dependants and this can limit their ability to seek help when faced with health symptoms. Women are also less likely to be able to finance health consultations—where they do not have command over household expenditure, for example, or where they earn less than men and are less able to afford user fees and charges. In some countries women also need to be accompanied when using services and are therefore dependent on someone being available and willing to take them (Baghdadi 2005; Simkhada et al. 2008).

Again the *World Health Survey 2005* is useful in that it provides data on the same measurement for a number of different countries. These surveys show various patterns of difference between women and men in their use of healthcare. For example, in France, India, the Russian Federation, and China more men than women reported using primary care from general practitioners, community services, and outpatient care in the past 12 months. More women than men reported receiving inpatient treatment in Portugal, Malawi, and China, but in France and the United Kingdom more men reported such treatment. However, in all of these countries more men than women reported not using any form of healthcare in the previous 12 months.

More recent national survey data on use of care is not available for all countries. However figures for the United Kingdom reveal that women consult more often than men throughout the healthcare system and also take more prescribed medication. Similar gendered patterns of consultation are also found in the United States and Australia (Wilkins et al. 2008; Sondik et al. 2012).

There are further differences between women and men in terms of what they are treated for. For example, in general practice in the United Kingdom more women than men are treated for hypertension, depression, and anxiety while men are more often treated for CHD and diabetes (Wilkins et al. 2008). The difference in treatment for depression is particularly wide, with more than twice as many women as men diagnosed with this illness. However, men are more frequently hospitalized for mental health problems, particularly in younger age groups.

Overall, data on consultation suggests that women do consult more often than men, and are more likely to use healthcare although patterns vary between countries and also in response to other factors including age. However, gender-linked influences, including financial or cultural constraints, for example, limit their use of services in some countries and may help explain variations in the gap between women and men.

Composite health indicators

The third way in which we can assess the health differences between women and men is through composite indicators of health at population level. One of the best known of these is the estimate of HALE produced by the WHO (see Table 10.2.2). HALE is a measure which begins with life expectancy at birth and is then adjusted downwards to reflect an estimate of time spent during the life course in poor health (Salomon et al. 2012). This estimate is carried out for each of WHO's member countries, using a range of survey statistics and other measures to calculate the adjustment separately for men and women.

Figures for 2010 revealed that global HALE at birth for men was lower than for women (58 years compared with 62 years)

Table 10.2.2 Differences in male and female healthy life expectancy (HALE), 2010—selected countries

Country	Male HALE	Female HALE	Difference in years (negative = female advantage)
Russian Federation	55	64	–9
Estonia	61	67	–6
Sri Lanka	62	67	–5
Côte D'Ivoire	45	50	–5
Republic of Korea	60	64	–4
China	65	69	–4
Angola	49	53	–4
Czech Republic	64	68	–4
Egypt	57	60	–3
Sierra Leone	47	50	–3
Cambodia	56	59	–3
South Africa	49	52	–3
Finland	64	67	–3
Samoa	59	62	–3
India	55	57	–2
Nepal	57	59	–2
Pakistan	55	57	–2
Cameroon	49	51	–2
United States of America	65	67	–2
Australia	67	69	–2
Kenya	54	56	–2
United Kingdom	66	68	–2
Iceland	65	67	–2
Somalia	47	48	–1
Niger	48	49	–1

Source: data from *The Lancet*, Volume 380, Issue 9859, Salomon, J.A. et al., Healthy Life Expectancy for 187 Countries, 1990–2010: a systematic analysis for the Global Burden Disease Study 2010, pp. 2144–62, Copyright © 2012 Elsevier Ltd. All rights reserved.

(Salomon et al. 2012). Women, however, lose a greater proportion of their healthy years to disability, due to their longer life expectancy. Trends in recent years show that women have gained more than men in both life expectancy and healthy life expectancy (Salomon et al. 2012). However, as with mortality and life expectancy, the extent of female advantage varies. In the Russian Federation, for example, female HALE at birth in 2012 was more than 8 years greater than male HALE, with similarly wide gaps in other East European countries. In France, Germany, and the United Kingdom women had only 2 or 3 years' advantage, while in countries such as Mali, Nigeria, and Somalia, with lower levels of life expectancy, the female advantage in terms of HALE was also low. Again, it is interesting to compare these figures with self-reported health—particularly those which show that women in the Russian Federation are less likely than men to describe themselves as having good health.

An alternative measure of health, using DALYs, highlights the distribution of the burden of disease and combines data on death with data on poor health and disability. DALYs are based on calculations of the value of years of disability-free life which are lost as a result of either premature death or the onset of disability (Murray et al. 2012). DALYs can be used in relation to specific conditions as well as overall health and indicate the value of particular interventions which reduce mortality or disability, such as health promotion or clean water policies. Worldwide, an estimated 2.5 billion DALYs are lost annually due to various health conditions (Murray et al. 2012). Nearly 35 per cent of these are due to infectious and parasitic diseases, including HIV/AIDS and tuberculosis which account for nearly 5 per cent of the total, and diarrhoeal diseases which account for 4 per cent (Murray et al. 2012). Heart disease contributes 11 per cent of lost DALYs, injuries a further 11 per cent, and mental health problems account for around 7.5 per cent of the total number of DALYs lost each year.

Overall, there is a narrow gap between women and men in their experience of morbidity using this measure: men make up 55 per cent of total DALYs lost per annum while women make up 45 per cent (Murray et al. 2012). However, men are much more likely than women to experience illness or disability, as well as premature death as a consequence of accidental and non-accidental injury, and have higher numbers of DALYs lost due to heart disease, alcohol and drug use disorders, and cancer. Males also have higher numbers of DALYs lost for neonatal disabilities. Healthy years lost by women are especially likely to result from complications of pregnancy and childbirth, depression and anxiety, and nutritional deficiencies. DALYs related to reproductive health including maternal disorder, disability arising from pregnancy and childbirth, sexually transmitted infections, gynaecological disorders, and cancers of the reproductive organs, account for around 5 per cent of the female burden of ill health but only 1 per cent of male DALYs (Murray et al. 2012).

DALYs have been criticized for various reasons which have a gendered dimension. The mental health aspects of rape and sexual violence, for example, are not counted by the DALYs approach and they focus on economic rather than social costs of disease and poor health—the loss of income or the costs of care, for example, rather than suffering, stigma, and individual well-being (Sen and Bonita 2000). This needs to be borne in mind when using DALYs to assess the gender gap in health, as there may well be variations between women and men in the social impact of different diseases.

Summary—differences between women and men in morbidity

The various ways of counting morbidity or ill health among women and men suggest a complex relationship between sex, gender, and health, which is mediated by age. Other factors such as socioeconomic status, for example, also play a part. While the picture for mortality is relatively straightforward, with most countries showing poorer life expectancy and higher death rates among men, morbidity data suggest that patterns for ill health vary for men and women around the world. On the whole women report poorer health, use services more, particularly where healthcare is relatively accessible, and experience more of some conditions especially those associated with chronic ill health. However, men experience higher levels of illness and disability from those conditions which also contribute to their higher mortality rates.

Sex and gender influences on health are central to explanations of these differences. The next section discusses what is meant by these terms and how they might affect health, before considering their contribution to specific diseases.

Sex, gender, and health

In order to understand sex- and gender-linked influences on health, it is important to clarify what we mean by sex and gender. Despite increasing recognition of the various ways in which sex and gender can impact on the health of men and women, the terms are still sometimes used wrongly. In particular, while ‘gender’ is now found more often than in the past in biomedical literature, it is often used interchangeably for ‘sex’ rather than as a distinct concept with a very different meaning (Doyal 2001; Krieger 2003).

Sex and health

‘Sex’ refers to biological influences including not only differences between women and men based on the reproductive system, but also those reflecting genetic and hormonal factors. For many years reproductive differences between women and men were seen as the most significant sex-linked influence on health. However, research in the past two decades has widened our understanding of the complexity of sex-linked factors on men’s and women’s health.

The Committee on Understanding the Biology of Sex and Gender Differences, set up by the Institute of Medicine in the United States in 1999, produced an important review of the evidence relating to biological factors and their effects on health. The final report concluded that ‘sex matters’ (Wizeman and Pardue 2001). That is to say, the health of men and women is influenced in important ways by ‘genetic, biochemical, physiological, physical’ elements, as well as those which are social in origin (Wizeman and Pardue 2001). While hormonal and reproductive factors play a part in patterns of health and in vulnerability to different conditions, this review also highlighted the significance of genetic and molecular factors, and important differences between men and women in gene expression. The report concluded with a number of recommendations for further research in the field, stressing that genetic factors are not fully understood as yet.

The range of sex-linked influences on health

Sex-linked factors play a key part in human health throughout the life course. Males are more vulnerable to mortality than females at every age, from conception onwards (Waldron 1985). For example, studies of fetal mortality—deaths in the womb at any gestational age—reveal higher mortality among males than females (MacDorman et al. 2007). Indeed the higher rate of male deaths prior to birth is an important indication of the part played by biological factors in male excess mortality.

Hormones play a key role in differences in health experience between women and men. Female sex hormones appear to protect women against a range of conditions including, for example, ischaemic heart disease (Waldron 1985). One explanation for this advantage is that oestrogen increases the flexibility of the female circulatory system, and that high blood pressure is less damaging for premenopausal women (Bird and Rieker 2008). Similarly, oestrogen affects cholesterol, increasing high-density lipoprotein cholesterol levels and decreasing low-density lipoprotein

cholesterol, and improves the functioning of the heart (Wizeman and Pardue 2001). However, evidence on the role of biology is mixed and inconclusive (Vaidya et al. 2011).

Hormones are also implicated in irritable bowel syndrome, another condition where there is a female excess. Women are up to four times as likely to suffer from this chronic painful condition. While this reflects gender-linked factors such as stress and anxiety, there is also evidence that men may receive protection from testosterone while female hormones may increase the severity of the symptoms experienced (Cain et al. 2009).

Hormonal changes across the menstrual cycle also appear to affect health outcomes for women in the context of interventions as diverse as smoking cessation and surgery for breast cancer (Kucuk and Atalay 2012). Further evidence of biological influences comes from research on alcohol-related damage. Women and men have different patterns of risk from alcohol consumption. Women suffer the adverse effects of alcohol in terms of brain and liver damage more quickly than men do and are more likely to suffer health damage at the same level of consumption as men. These variations are partly due to differences in metabolism and hormonal factors, which mean that women’s bodies process alcohol differently (Redgrave et al. 2003).

There are also differences in male and female immune systems, which are related to reproductive factors, particularly the capacity of women to conceive and carry a child. These differences mean that women’s immune systems are more at risk from auto-immune disorders (Zandman-Goddard et al. 2012). Changes in the immune system of pregnant women put them at higher risk of some communicable diseases ranging from measles to malaria (Wizeman and Pardue 2001; Rieker et al. 2010). However, other pregnancy-related changes such as the tendency for auto-immune diseases such as rheumatoid arthritis to go into remission highlight the complexity of the relationship between sex and the immune system (Rieker et al. 2010).

Recent research has also suggested important sex differences in gene expression, contributing to women’s higher risks for some forms of cancer. For example, among smokers, women appear to be more at risk of lung cancer than men at the same level of smoking, and lung cancer is also more common among non-smoking women than non-smoking men (Paggi et al. 2010). This has been related to gene expression, simplistically defined as a process that allows a particular gene to come into play or not. Expression of genes related to lung cancer may be greater among women than men due to the location of the expressed gene on the X chromosome, leading to an increased risk of this cancer as well as shaping the type of lung cancer which women develop (Payne 2006; Paggi et al. 2010).

In addition, there is increasing evidence of sex differences in the way the brain is organized, including the use of language and verbal abilities (Wallentin 2009). For example, some studies report that women recover more language ability than men following a left-hemisphere stroke (Wizeman and Pardue 2001) but this is not a universal finding (Wallentin 2009). There are also differences between women and men in the way the brain responds to noxious stimuli, which in turn affect experiences of symptoms such as pain. Women have higher prevalence rates for what are often described as ‘pain conditions’, including headache, abdominal pain, and facial pain (Popescu et al. 2010). While this reflects the fact that the expression of pain is culturally more sanctioned

for women than men, biological factors also play a part, especially differences between women and men in particular neurological pathways (Popescu et al. 2010).

However, we must be wary of attributing too much to biology. For example, research on the relationship between parity and some health conditions, especially non-reproductive carcinomas such as colorectal cancer, has suggested that there might be a relationship for women between pregnancy and subsequent health risks. But recent studies have also revealed a similar relationship between parity and mortality for men, implying that social factors such as stress, access to resources, and expectations associated with having children may be more significant than biological factors in this association (Jaffe et al. 2011).

Wizeman and Pardue (2001) point out the limitations in this area of knowledge. Despite many years of research on the ways in which biology impacts on health, conclusive evidence and clear understanding of the pathways concerned remains scarce. There are various reasons for this, including a lack of research which is disaggregated for men and women and the fact that research findings which fail to find a difference between women and men are often not published, despite the fact that such results also advance our understanding.

We should also note that some writers have challenged the way in which biology, in particular, has been used in an overly simplistic way. Springer et al. (2012) for example, take issue with Wizeman and Pardue's statement that 'every cell has a sex', arguing that biological sex has been 'reified' as a dichotomous variable, separate from gender influences, and is often treated as more important in the health of both women and men. However, biology or sex-linked factors interact with environmental factors, including gender differences.

Gender and health

'Gender' refers to socially constructed differences between women and men, that is, the conventions, roles and expectations of men and women which are culturally ascribed (Krieger 2003). Gendered influences on health include access to health-promoting resources, exposure to health damaging and health promoting factors in daily life, and different expectations of behaviour such as drinking alcohol, risk-taking, and the use of healthcare. In addition, gender impacts on health through the ways in which health services are organized and delivered, particularly when such services operate in gender insensitive ways.

One of the key differences between sex and gender is the extent to which they are fixed, or can change over time. Sex—male or female—is assigned to a child at birth on the basis of external genitalia, and is fixed other than for a minority of people undergoing medical sex reassignment. Gender is generally ascribed on the basis of biological sex, although what is meant in any one society or culture by gender may vary over the years and between social or other groupings. Thus a child is identified at birth as either male or female and this in turn leads to the categorizations embedded in masculinity or femininity in that society.

Gender is also an important influence on the health of men and women through what is described by Springer et al. (2012) as the 'entanglement' between biology and gender. Krieger and Zierler (1995) describe such interactions in terms of the *biological expression of gender* and the *gendered expression of biology*. The biological expression of gender refers to the ways in which gender becomes

embodied. For example, in many societies gender is constructed to mean that women see themselves, and are seen by others, as weaker than men. This can result in women taking less exercise, or choosing less strenuous forms of activity, which in turn affect the female body. The gendered expression of biology refers to the ways in which biological understandings of women and men lead to gendered differentiations, which often take the form of discrimination. So, for example, women's reproductive capacity is used to justify their exclusion from some forms of paid work on the basis that it is unsafe. Similarly their exclusion from medical research is said to be justified on the basis that it may cause harm to an unborn child. This then strengthens social constructions of gender in which women are seen as less able to undertake some forms of paid work, or less vulnerable to some forms of disease.

For many writers, gender is seen as something that is 'performed' in various ways, in exchange with other people. That is, we 'do' gender in our daily lives—in our paid work, in relationships, in leisure activities, and so on (Courtenay and Messerschmidt 2011). This view of gender allows us to see how it changes over time and across societies, and also how individuals might 'do' gender differently at different times and in different settings. In addition, it highlights the fact that what is appropriate gendered behaviour for one group may not be so for another—gender roles vary according to class and ethnicity for example. Finally it allows for the possibility that individuals might choose to adopt gender roles which are not commensurate with their biological sex. But while various gender roles may be available, it is also the case that in all societies some forms of masculinity and femininity are more sanctioned than others and this may impact on health in negative or positive ways.

Many writers have observed that in most if not all cultures, masculinity is privileged over femininity, but it is also true that not all men are equally advantaged. The term 'hegemonic masculinity' refers to the most privileged form of masculinity, typically occupied by white middle-class men (Connell and Messerschmidt 2005; Connell 2012). Men occupying different class positions may experience masculinity in a range of ways, with associated health benefits and/or risks. Similarly, women's experiences of gender interact with other positions or social practices, again with varying health consequences.

Gender affects the health of both men and women in a number of interlocking ways. Firstly, gender mediates the effect of physical and psychological risks encountered in daily life. There is substantial evidence, for example, that material factors such as poverty and social exclusion, socioeconomic status, poor housing and environmental disadvantage, occupation, and unpaid work all impact on health in varying ways and to varying degrees (WHO 2008). And men and women may face differential risks of experiencing these adverse effects, because of their gender. Secondly, gender roles and expectations are closely associated with individual behaviour which in turn may impact on the health of women and men.

Socioeconomic determinants of health and gender

Material factors influence the health of women and men in complex ways through aspects of daily life such as paid work and employment status, household work and domestic labour, income, caring responsibilities, living arrangements, and experiences of conflict, stress, and violence. The extent to which men and women

are exposed to these risk factors, and how they impact on their health, varies in relation to geographical location, socioeconomic status, and cultural differences (WHO 2008).

Paid employment exerts numerous effects on health. There are a range of hazards associated with particular jobs, including exposure to unsafe chemicals, hazardous work environments, and dangers inherent in the nature of the work itself. The gender division of labour, which sees men more often employed in certain sectors and in certain occupations within sectors, creates a gendered division of occupational risk. Men typically work in industries and in jobs with a higher mortality risk—including construction, transport, and the emergency services, for example.

However, in recent years the occupational injury gap between women and men has narrowed, following a rise in the numbers of women in the labour force, and there has been a corresponding increase in some forms of injury-related mortality among women (WHO 2008; Forastieri 2010). Other work-related hazards affect the risk of poor health—repetitive strain injury, for example, from keyboard work and some production processes in manufacturing. Such injuries are more common among women partly as a result of the jobs they occupy, and partly because the design of workstations is often based on male rather than female physiology (Forastieri 2010).

Gender differences in occupational risk are compounded by differences outside the workplace and in particular by gender differences in domestic work. Women still carry out most household chores. For example in the United Kingdom despite their increasing participation in paid work, women still spend on average twice as many hours per day as men in housework and childcare (Lader et al. 2006). In addition, even where men take on some of the work, women retain overall responsibility for domestic labour—for planning, organizing, and ensuring it is done. Domestic labour carries further implications for health including the stress of managing responsibilities, loneliness, and isolation, as well as the lack of an independent income and low status for those women who are not also employed. Women working at home are particularly vulnerable to mental health problems in comparison with those who have paid work but the strain of juggling two roles and the dual burden of paid work and domestic labour also puts women who enter the labour market at risk of poor mental health (Harryson et al. 2012).

Poverty and social exclusion also carry pronounced health risks for both men and women. However, there are gender differences in the risk of such poverty, with women in most parts of the world being more likely to be poor (WHO 2008). This is due to lower wages, working in the informal sector, reduced access to paid work as a result of caring responsibilities, and, in some countries, cultural restrictions, and also reflects that fact that women may not always share equally in household resources. Poverty is often especially severe among older women whose health is already frail (WHO 2003).

Exposure to violence creates further risks including poor mental health, post-traumatic stress disorders, and physical injuries. Violence is one of the most important causes of death for younger age groups (WHO and LSHTM 2010) but there are marked gender differences not only in the level of risk from violence but also in the source. Although both women and men are at risk from interpersonal violence, violence against men is more common in the public domain, and they are more at risk from strangers. However, women are more likely to be exposed to violence in the

home—from partners and members of their family (WHO and LSHTM 2010). Women are at particular risk from sexual violence both in the home and elsewhere, and the consequences for their health can include pregnancy and sexually transmitted infections as well as mental health problems. Although sexual violence against men is less common, and in the past there has been too little research on this, it may be especially damaging for mental health due to feelings of stigma and shame (Sivakumaran 2010).

Taken together these material aspects of daily life can create particular health stresses which are often different for men and women. To these health risks, we can add those associated with ‘doing gender’—the ways in which social constructions of masculinity and femininity are associated with the increased risk of particular behaviours which further impact on health.

‘Doing gender’—masculinity, femininity, and health

Behaviour has long been seen as the leading gendered explanation for men’s poorer health and premature mortality. In the seventeenth century, John Graunt suggested that women lived longer than men despite their experiences of illness because, ‘Men, being more intemperate than Women, die as much by reason of their Vices, as Women do by the Infirmary of their Sex’ (Graunt, cited in Ciocco 1940, p. 61). There are still important differences between women and men in behaviours such as smoking, alcohol and substance use, physical activity, diet, risk-taking, and the use of healthcare services including preventive care and screening. These differences taken together are a key part of the explanation for men’s higher mortality; a number of writers in this area have highlighted the extent to which masculinity, in particular, accounts for the greater mortality risks experienced by men across a range of cultural settings (Courtenay and Messerschmidt 2011).

One of the most damaging behaviours—smoking and tobacco use—has a strongly gendered history. More men than women die each year from smoking-related diseases: lung cancer, for example, killed twice as many men as women worldwide in 2002 (WHO 2009). This reflects the gender ratio in smokers: throughout the world more men than women smoke and in countries where the epidemic is relatively new the great majority of those using tobacco are male (Erikson et al. 2012). In Malaysia, for example, 53 per cent of men smoke compared with less than 3 per cent of women; in Malawi 26 per cent of men and 4 per cent of women smoke, while in Bangladesh the figures are 46 per cent and 2 per cent (Erikson et al. 2012).

However, more developed regions where smoking has a longer history have seen increasing numbers of women using tobacco, to the point where in some countries similar proportions of women and men are smokers: in Norway and Sweden, for example (Erikson et al. 2012). Alcohol and substance use also have gendered profiles. Excessive consumption of alcohol on a regular basis is associated with an increased risk of a number of diseases, including cirrhosis of the liver and other liver disease, some forms of CHD and mouth cancers (WHO 2011c). Other forms of alcohol consumption, including what is sometimes referred to as ‘binge drinking’ where high levels of alcohol are consumed over a short period of time, also lead to an increased risk of violence and accidental injury, as well as self-harm and suicide (WHO 2011c).

National and international data show that more women than men can be described as ‘abstainers’, that is, as non-drinkers. The extent of the gender gap varies: in the Philippines, for example,

women are three times more likely than men to be lifelong abstainers, while in Iceland the ratio of female to male abstainers is nearly 2:1 (WHO 2011c). When we look at men and women who are defined as drinkers, men usually consume more units of alcohol on a weekly basis and/or have a high daily intake. Per capita consumption is higher for women than men in only one country, Ecuador, while in all other countries men drink more than women (WHO 2011b). In Bosnia and Herzegovina, for example, male per capita consumption was twice as high as female consumption, and in South Africa it is 1.6 times higher.

If we look at heavy episodic drinking, defined as drinking heavily on at least one occasion in a 7-day period, this is also more common among men than women around the world. Nearly half of men in Ireland, for example, report such levels of consumption compared with 14 per cent of women, while other countries with high levels of male binge drinking include the Czech Republic, Botswana, and Paraguay (WHO 2012c). In England, in 2011, more than 39 per cent of men, compared with 28 per cent of women, reported drinking more than the daily recommended units on at least 1 day in the previous week (Craig and Mindell 2012) and in Australia, men were three times as likely to drink more than daily or weekly recommended limits (Australian Bureau of Statistics 2012).

Among young people, heavy episodic drinking is also more common among men (WHO 2011c) and while increases in binge drinking among young women in some high-income countries have led to concern, it remains the case that this behaviour is more frequent for males (Emslie et al. 2009).

Diet is also an important, modifiable, contributor to health risks. The influence of diet on health is becoming increasingly clear, with growing evidence suggesting that a diet which is rich in fruit, vegetables, and fibre and low in fat may reduce the risk of various health problems including cancer and heart disease (World Cancer Research Fund and American Institute for Cancer Research 2007). Gender differences in what we eat may therefore play an important role in explaining different patterns of health for men and women. Men are more likely than women to die from colorectal cancer, for example, and part of the explanation for this seems to stem from differences in diet (Payne 2007).

On the whole, men's diets are less healthy than those of women, particularly in high-income countries, where men are more likely to consume inadequate amounts of vegetables and fruit and also to eat higher than recommended amounts of red meat (Payne 2006; Craig and Mindell 2012). More women than men in Australia, for example, report meeting recommended levels of fruit and vegetable intake (Australian Bureau of Statistics 2012). However, in low- and middle-income countries, particularly those where food is scarce, women and girls are less likely than men to be eating adequate levels of fruit and vegetables. In Malawi, for example, 42 per cent of women and 37 per cent of men have diets with less than the recommended amount of fruit and vegetables. In other low-income countries, including Pakistan, Swaziland, and Kenya, a large majority of both men and women report diets insufficient in fruit and vegetables and the differences between them are slight (WHO 2005). In these countries, where there is a high risk of food insecurity, there are important gender differences in the distribution of food within households, in expectations about what men and women will eat, and also in what will be given to male and female children.

However, food intake and diet also need to be set against energy requirements and again there are important gender differences both in levels of physical activity and in kinds of activity. In high-income countries lack of physical activity is a health concern which has increased in prominence in recent years. Physical activity can have a positive effect on health. It helps to protect against heart disease and may play a part in reducing vulnerability to other conditions, including some cancers and mental health problems (WHO 2009). The WHO estimates that physical inactivity is the fourth leading risk factor for global mortality, associated with 27 per cent of diabetes DALYs, 25 per cent of breast and colon cancer DALYs, and 30 per cent of cardiovascular DALYs (WHO 2010). Physical activity levels in most communities are different for men and women, although the size of the gap varies in relation to other factors including employment-related activity and available leisure time.

Data on activity are complex, and not always comparable. Some surveys refer to total physical activity including that associated with work and travel—cycling and walking, for example—as well as leisure activities such as sport. One of the problems with this data is that physical domestic work, mainly carried out by women, is often not included in such measures (O'Brien Cousins and Gillis 2005). This means that some figures, particularly those in low- and middle-income countries, based on total activity, overestimate the extent to which women are leading sedentary lives. Data based on sports leisure activity, however, might also miss out some activities which are more frequent among women—dancing, for example (O'Brien Cousins and Gillis 2005).

Data in high-income countries often focuses on leisure activity rather than total activity, making it difficult to compare findings with poorer countries. Such data show a gap between men and women in time spent in physical activity, with men tending to be more active. In the United States, for example, a higher proportion of men participate regularly in physical activity and women are more likely to be insufficiently active (Sondik et al. 2012). Similarly, in England, more men than women achieve 'recommended' levels of physical activity, with the widest gap in young adults between 16 and 24 years of age (Craig and Mindell 2012).

Figures for total physical activity in low- and middle-income countries suggest that men might be more likely than women to have active lifestyles, although this is likely to reflect a failure to count some aspects of women's activities. In Kenya, for example, while less than 10 per cent of adults report physical activity levels which are too low, women are slightly more likely than men to report insufficient time spent in physical activity (WHO 2005). Similarly in Malawi, few people have low levels of activity, but activity levels are lower among women than men. Activity levels are slightly lower in Pakistan, where women are twice as likely as men to report insufficient activity; and in India and China women are also less likely than men to report sufficient levels of activity.

However, in these countries it is also important to consider activity, or energy expenditure, alongside diet and calorie intake. In the poorest countries women, in particular, experience health risks because of activity levels that are high in the context of too little food. These problems are especially severe for pregnant and breastfeeding women and carry long-term implications both for their health and that of their child. Jackson and Palmer-Jones (1998), for example, talk of an 'energy trap' resulting from development policies which aim to increase various kinds of work in order

to reduce poverty but which fail to take account of the increased need for food created by increased levels of activity. Gender differences in food allocation and access to calories, as well as in work carried out, mean this is a particularly acute problem for women (Patel 2012).

Diet and activity levels in high-income countries are also connected to a further health risk: obesity. Obesity is associated with various diseases including CHD, some forms of cancer, and diabetes. Obesity, defined as a body mass index (BMI) over 30, is generally more common among women than men, although this varies between countries, and more men than women are defined as overweight (with a BMI of between 25 and 30) (WHO 2012b).

In England, in 2011, 65 per cent of men were overweight or obese compared with 61 per cent of women (Craig and Mindell 2012), while in Australia 70 per cent of men were overweight or obese in 2011–2012 compared with 55 per cent of women (Australian Bureau of Statistics 2012). Similarly, in the United States, 69 per cent of men compared with 55 per cent of women were overweight or obese (Sondik et al. 2012). In older age groups and in lower-income groups in particular, women are more likely than men to be defined as obese (Zaninotto et al. 2006).

A final gendered aspect of behaviour which affects health and mortality risk is the use of preventive services and healthcare. We have already discussed gender differences in consultation as a measure of morbidity, and highlighted the role of economic factors in the use of healthcare, but it is also important to consider the ways in which men and women differ in help-seeking behaviour. A number of studies have suggested that men are reluctant to seek medical help and attend services less readily than women. As one man put it, ‘I don’t go to the doctor unless something scares the hell out of me’ (Stibbe 2004, p. 36). Men describe themselves as unwilling to make a fuss or waste the time of health professionals (Courtenay and Messerschmidt 2011).

Although there are a number of variations in data on health service use, reflecting age and socioeconomic differences, for example, overall men do appear less willing to see themselves as in need of healthcare. Men are more difficult to engage in health promotion activities including screening, leading some healthcare providers to devise various gender-sensitive strategies to increase take-up among men, such as placing clinics and information points in workplaces and bars (Wilkins et al. 2008; Courtenay and Messerschmidt 2011).

Overall, gender differences in roles, expectations, and behaviour combine to increase the risk for men of premature mortality and the risk for women of chronic health problems (Snow 2008). Masculinity, insofar as it involves risk-taking and unhealthy behaviours, increases risks of accidental and non-accidental injury, non-communicable diseases associated with smoking, alcohol, and substance use. Masculine practices also increase some health risks for women, particularly the risks associated with male violence and sexually transmitted infections.

Female gender roles and expectations may lead to reduced risks for some conditions, due to lower rates of smoking, alcohol and substance use, better diets, and less risk-taking, although the lower rates of physical activity more common among women will also affect their health risks. In poorer countries however, women have different problems associated with insufficient food for the work they are expected to carry out. There are also pressures on both men and women arising from the stress of

gender role expectations, particularly in relation to failure to meet expectations.

In order to illustrate these different influences and the complex associations between sex and gender we turn now to look at specific health problems: cardiovascular diseases, cancer, mental health difficulties, HIV/AIDS, and malaria.

The impact of sex and gender on specific health problems

Cardiovascular diseases

Cardiovascular diseases include CHD and stroke. Taken together, cardiovascular diseases account for around one-tenth of the global burden of disease, with more men than women affected. CHD is the major contributor to this burden, particularly among men, while strokes account for similar levels of illness among men and women. These conditions are also important in overall mortality: more men than women die as a result of CHD but women are more likely to die from a stroke (WHO 2012f). One of the key differences between women and men in these illnesses is the age at which risk increases: men are more likely than women to die prematurely from CHD and the male to female ratio is greatest in mid-life. Women with CHD die on average 10 years later than men (Wizeman and Pardue 2001). In the United Kingdom, for example, the male mortality rate for CHD among those aged 45–54 is nearly five times higher than the female rate, but by the age of 75 female deaths outnumber those of men (Scarborough et al. 2010). Men’s greater risk of premature death and illness for CHD is found throughout the world (Riska 2010).

Why do men have higher risks than women for CHD at an early stage in the life course? In the aetiology of CHD, raised blood pressure and blood cholesterol are significant risk factors, and behaviours which are more common among men than women—particularly poor diet and smoking—are important underlying explanations. While women gain protection from heart disease due to female hormones, men increase their risks through their adoption of risky behaviours. The later age at which women appear to be at risk of CHD has led to speculation that until the menopause female hormones might offer women some degree of protection. However, most recent research has failed to support this suggestion. For example, women’s CHD risk does not increase immediately following the menopause but some years later, suggesting that other factors may be important instead of, or alongside, female hormones. In addition hormone replacement therapy does not appear to offer women protection from CHD, indeed it might actually increase their risk (Riska 2010).

However, there are also concerns over possible differences between women and men in the recognition and treatment of CHD. Because heart disease is seen as primarily a male condition, women may be less likely to have their illness diagnosed or to be offered appropriate treatment (Riska 2010). This is dealt with further later in this chapter.

Cancer

Overall mortality from cancer is higher among men, and while both men and women are vulnerable to reproductive-related cancers, men are also more likely than women to die from cancers related to particular lifestyles and behaviours (WHO 2011a).

Although cancers of the female reproductive organs lead to more deaths among women than male reproductive cancers do among men, the difference does not compensate for the male excess cancer mortality stemming from factors such as tobacco use, dietary influences, and alcohol consumption.

Lung cancer in particular accounts for more than twice as many deaths among men as among women (WHO 2011a). The main cause of lung cancer for both men and women is tobacco use and in countries where tobacco use remains a predominantly male habit, the male to female ratio is especially high (Erikson et al. 2012). In Thailand, for example, the ratio of men to women for lung cancer mortality is around 2.3:1, while in Denmark, where equal numbers of men and women now smoke, the ratio has reduced to 1.4:1 in recent years (WHO 2012e).

However, research suggests that the risk of lung cancer is different for women and men irrespective of absolute levels of tobacco use. These differences stem from both gendered differences in patterns of tobacco use—the type of cigarettes smoked, for example, and the depth of inhalation—and also biological factors. Women appear to have a greater biological vulnerability to lung cancer due to genetic factors while their greater use of low-tar cigarettes leads to an increased risk of one form of lung cancer—adenocarcinoma (Kiyohara and Ohno 2010). However, while lung cancer is a particularly fatal form of cancer with very low 1-year and 5-year survival rates, women also appear to have better prospects for survival in comparison with men and this too is related to biological differences between women and men.

Thus sex and gender-linked factors interact to produce different risks of cancer for women and men, reflecting both hormonal and genetic influences and the impact of certain behaviours.

Mental health and illness

Among chronic and debilitating conditions, the most significant in terms of numbers affected and the impact on daily living are those associated with mental illness. Mental health problems, including depression, anxiety, substance use, and schizophrenia, account for 11 per cent of the global burden of disease (WHO 2012f). Around 450 million people worldwide experience mental illness of one kind or another at any one time. There are important differences between women and men in their risks of various mental health problems. In particular more women are diagnosed as suffering from depression and anxiety-related conditions, and in community-based surveys more women are found to be suffering from symptoms of these illnesses (Payne 2006; Snow 2008). Figures for DALYs lost in 2010 due to mental illness show the total burden evenly divided between males and females. However, within that overall figure, women experience much more ill health due to depression and anxiety, in comparison with men.

Men on the other hand are more frequently treated for mental health difficulties associated with alcohol and substance use, including harmful use, dependence, and psychosis. Male DALYs for drug use disorders are more than twice as high as female DALYs, while those for alcohol related disorders are more than four times higher for men than for women (Courtenay and Messerschmidt 2011; Murray et al. 2012). Men are also more likely to commit suicide than women in virtually every country in the world, with deaths from suicide in 2008 twice as high among men as women (WHO 2011a). In contrast, more women than men carry out acts of deliberate self-harm.

While there is some evidence that biological influences play a part in shaping mental health—particularly in relation to conditions such as postnatal depression—most research suggests that gendered factors play the more significant role. These include stress-linked factors such as those associated with poverty, parenting, employment, exposure to the threat of violence and gendered expectations, as well as the extent to which gender stereotyping in mental health services affects the delivery of care by increasing diagnoses of depression among women. Under-diagnosis of depression among men may help to explain their higher rates of alcohol and drug use disorders, and higher rates of suicide (Wilkins et al. 2008; Courtenay and Messerschmidt 2011).

HIV/AIDS

In many parts of the world HIV/AIDS is one of the most significant threats to the health of both women and men. It is transmitted either through unprotected vaginal or anal sex, as a result of contaminated needles in the context of injecting drug use or from mother to child *in utero* or during breastfeeding. There were 2.7 million new infections and nearly 1.8 million deaths in 2010 (UNAIDS 2011). About 68 per cent of those who were HIV positive were living in sub-Saharan Africa, and around half of all AIDS-related deaths occurred in the same region (UNAIDS 2011).

The overall number of deaths has decreased markedly since the spread of antiretroviral drugs in the mid 1990s. Similarly, the number of new infections is declining in many parts of the world including 22 sub-Saharan countries. Nevertheless, there has been a marked increase in the number of people living with HIV which has risen by 17 per cent from 2001 to 2010 and is now estimated to be around 34 million (United Nations Development Programme 2012). This is due to the fact that levels of new infection continue to be high combined with the extended lifespan that accompanies greater access to HIV treatment.

Globally, the proportion of women living with HIV has now stabilized at around 50 per cent though they make up 60 per cent of those affected in sub-Saharan Africa. Young women are at particular risk: in South Africa, for example, 21 per cent of girls and young women aged 15–24 were HIV positive in 2010 compared with 7 per cent of men of the same age (UNAIDS 2011). This has led to high rates of mother-to-child transmission with about 90 per cent of all HIV-positive children in the world living in Africa. Women are making up an increasing proportion of the positive population in some parts of Asia, Eastern Europe, and South America.

Women are biologically more vulnerable than men to HIV infection. In unprotected vaginal intercourse, women are at greater risk than men because the vaginal wall is exposed to seminal fluid for a longer period of time. This is especially dangerous in the presence of traumatic injury or existing genital infections which are more likely to be found in women (Dunkle et al. 2004). The risk of transmission from a single heterosexual act is estimated to be around 0.04 per cent for females to males and around 0.8 per cent from males to females (Boily et al. 2009). However, it is important to note that anal sex is riskiest of all and this is most likely to affect men who have sex with men (MSM).

Turning to gender, women again have a particular vulnerability due to the fact that they are less able to negotiate sexual

relationships—to demand protection, for example—and may be forced or coerced into unprotected sex, especially at young ages. This is exacerbated by their lack of access to women-initiated or -controlled prevention methods. The example of the Asian region highlights this with particular clarity. In 1990, women made up some 17 per cent of the total HIV-positive population but by 2007 this had doubled to 35 per cent (UNAIDS 2009). Most had only ever had one sexual partner so that sex with their husbands can be a major threat to the health of many. This reflects the high rates of extra-marital sex among married men with both male and female sex workers who themselves are at very high risk of infection.

While men do not have the heightened physiological vulnerability we have noted in the case of women, the social construction of masculine gender may lead them to risk their health. While this can take many different forms it will usually include the social expectation that ‘real’ (heterosexual) men will ‘perform’ their masculinity through having frequent (often unprotected) sex with different women. A similar social pressure towards sexual performance is often found among those men who are active in gay ‘communities’.

HIV and AIDS have severe consequences for the well-being of both women and men. The initial stage of HIV involves a gradual decline in the capacity of the body to fight off opportunistic infections. Those who are positive are said to have acquired immune deficiency syndrome (AIDS) when their immune system has weakened to the point when they have one or several of what are called AIDS defining illnesses. These include *Pneumocystis pneumonia* and the virus-induced cancer Kaposi’s sarcoma. In women, cervical cancer is also regarded as an AIDS-defining condition when it occurs along with HIV infection. Without treatment, infections and malignancies increase in frequency, severity, and duration until death intervenes.

Relatively little is known about the differences between women and men in the biological development of HIV and AIDS. However, the evidence indicates that for men, the first opportunistic illnesses are more likely to be cytomegalovirus, Kaposi’s sarcoma, or oral hairy leucoplakia while for women they are more likely to be oesophageal candidiasis or toxoplasmosis (Women’s Health Research 2009).

Untreated HIV infection also poses a particular threat to women during pregnancy. In sub-Saharan Africa, seropositive status is becoming increasingly important as a cause of maternal morbidity and mortality (Black et al. 2009). Since 1998, HIV has been the leading indirect cause of maternal deaths in South Africa, reversing a previous decline in mortality rates. A recent study showed that HIV-positive women in Johannesburg were around six times more likely to die from maternal causes than their negative counterparts (Black et al. 2009).

In most parts of the world there are also marked gender differences in use of HIV services. As the pandemic became increasingly ‘feminized’ it was widely assumed that women were missing out on treatment compared with men. However, recent studies have shown that in many settings it is actually (heterosexual) men who have least access to services relative to their needs (Natrass 2006). This reflects both women’s greater likelihood of diagnosis in the context of maternity care and also men’s reluctance to engage in medical encounters which appears to be especially significant in the context of HIV (Skovdal et al. 2011).

Thus sex and gender again intertwine both in terms of men’s and women’s vulnerability to infection and in the consequences of the disease. However, in the case of HIV the intersections between sex and gender need to be understood in the context of sexual identities and practices.

Malaria

In 2010, there were between 150 and 290 million cases of malaria, and around 660,000 people—mainly children—died from this disease (WHO 2012g). These figures are falling in comparison with earlier years. The global impact of malaria on the burden of illness is calculated at more than 1 million DALYs per annum (Murray et al. 2012). The vast majority of those affected by malaria live in sub-Saharan Africa.

Reducing the incidence of malaria (along with HIV/AIDS and tuberculosis) was part of the eight Millennium Development Goals and has been a key focus of the work of the WHO. Malaria incidence reflects a range of factors—increasing resistance to the drugs used to treat the disease and to insecticides used to prevent transmission, lack of access to necessary medicine and to preventive measures particularly in poorer countries, and deforestation in some areas creating wider vectors of transmission. However, figures in the first decade of the twenty-first century suggest the efforts of global organizations such as the WHO and The Global Fund have met with some success as prevalence and deaths have fallen, despite a slowing down in the rate of improvement more recently (WHO 2012g).

There are important differences between women and men in the risk of malaria and these have changed in the last few years. In comparison with earlier periods when there was an excess of female deaths, in 2008 20,000 more males than females died of malaria (WHO 2012g). This is due to 24,000 more male deaths compared with female deaths among children under 5—in every other age group more females die of malaria. This pattern reflects both sex- and gender-based influences. For example, women’s risk of contracting malaria increases in pregnancy, due to temporary changes in the immune system and this biological risk factor is reflected in the slight over-representation of female deaths worldwide during reproductive years. Gender factors can also play a part where women have less access than men to preventive measures such as bednets treated with insecticide, due to household division of resources. In addition, women’s responsibility for work, such as water collection and some agricultural labour, increases their exposure to mosquitoes and their risk of being bitten. Studies have also found women to be less well informed than men about the risks of malaria and about means of protection, while women in some cultures are less able to access healthcare when infected because they have less control over household resources and because they may need to be chaperoned when attending health services (Tanner and Vlassoff 1998).

Gender and the delivery of healthcare

The final way in which gender impacts on health is through the delivery of healthcare. In addition to material circumstances and behaviour, the health of both men and women is also associated with the way in which healthcare is provided and we need to ask if health services are equally available for women and men, if they are accessible and if they are appropriate.

Gender differences in availability and access

There are a number of ways in which gender affects access to healthcare. Most importantly perhaps, gender affects the resources that are necessary in order to use health services. Around the world women earn less than men, and, where health insurance is related to paid work, are more often in jobs without insurance cover (Payne 2006). In the United States, more men than women do not have a 'usual place' of healthcare, and more men use hospital emergency rooms; while women make more visits to healthcare than men (Sondik et al. 2012).

In many low- and middle-income countries, while both men and women experience difficulty in obtaining healthcare due to the location of services and the need to meet the costs of user fees, women are particularly disadvantaged due to lack of independent income or say in how household resources are used (Baghdadi 2005; Sen and Ostlin 2007).

In addition to access, there may be further differences in availability. Where services are only open during the day they are less available to those with paid work who cannot take time off, or to those whose caring responsibilities prevent attendance. While more men are prevented from using daytime services due to employment, they are also more often in jobs where time off for medical appointments is sanctioned. For women juggling full-time or part-time work with childcare, seeking medical help may be particularly difficult.

Similarly some cultures require women to consult with female health professionals who may not always be available. Even where it is not culturally prescribed, women are more likely to report a preference for a female clinician, particularly when consulting about intimate health problems. For example, women are more likely to prefer a female colonoscopist when being screened for bowel cancer, but the lack of women in this profession means their preferences are often not met, potentially delaying detection of bowel cancer among women (Menees et al. 2003; Chong 2012).

Gender differences in the quality of care

The second way in which gender impinges on healthcare is through differences in the quality of care offered to men and women. One important factor affecting this is medical knowledge. Medical research has for some time been criticized for failing to disaggregate findings for women and men and for failing to include women in studies of health problems affecting both sexes (Doyal 1998). This focus on male subjects is problematic when it is assumed that findings can be extended to female populations as though there is no difference. Both symptom recognition and treatment which is based on men may fail women—women metabolize pharmaceuticals differently to men, for example, and prescribed drugs may be more or less effective, or carry different risks for women when research was conducted on men (Wizeman and Pardue 2001). Similarly, risk factors affecting women's health tend to have been less intensively studied: health risks associated with housework, for example, rather than the question of role strain, have only been explored relatively recently compared with the health risks of traditionally male occupations (Artazcoz et al. 2007).

In the United States, research funded by the National Institutes of Health has been required since 1994 both to include sufficient numbers of men and women, and members of minority ethnic groups, and to provide separate analyses and reporting of results.

Despite this there is evidence that there are still a number of studies either focusing on men alone or failing to disaggregate findings for men and women and there is still room for improvement (Vidaver et al. 2000; Geller et al. 2011). In countries without such guidelines the bias is even greater.

Studies have also explored the different ways in which services respond to women and men. Women are less likely to have heart conditions recognized by their primary physician, for example, because they often present with atypical symptoms including fatigue, shortness of breath, or cold sweats. Men on the other hand are seen as candidates for heart complaints by themselves, by their families and by healthcare workers, and the symptoms men typically present with have become the norm (Riska 2010). In addition, chest pain, a key symptom of heart disease, is more likely to have other causes for women than men which can lead to under-diagnosis of heart disease. Not surprisingly, perhaps, women are less often referred both for tests and for treatment, and tend to be at a more advanced stage of illness when they are treated, with the risk this implies (Governder and Penn-Kekana 2008).

Equally, men are less likely than women to have mental health problems such as depression recognized (Wilkins et al. 2008). Under-diagnosis and under-treatment of depression in men contribute to higher rates of male suicide mortality; where there have been increases in prescriptions of antidepressants among men, suicide rates have fallen (Gunnell et al. 2003).

In addition, healthcare may not be sensitive to more subtle gender differences in health needs. Some services are gender blind and unknowingly discriminate against men or women by failing to identify their specific needs. For example, most smoking cessation interventions do not highlight gender differences in successful strategies, including the fact that women and men appear to smoke for different reasons and may take up smoking again in response to different stress factors (Samet and Yoon 2010). In addition, women metabolize nicotine differently to men, and have more adverse reactions to withdrawal in comparison with men (Perkins 2001). Women and men also may need different kinds of support, both from friends or family and from health services (Samet and Yoon 2010).

Conclusion

What we have seen in this chapter is that both sex and gender play an important part in shaping the health of men and women, alongside other forms of diversity. Sex, or biology, is more than reproduction. The health of both men and women is also affected by hormonal differences, and by genetic factors, which impact on vulnerability to different diseases as well as the chances of recovery and survival. Gender, or socially constructed difference, also affects health—by increasing the chances of exposure to specific risk factors, such as poverty, or by helping to shape the behavioural choices made by men and women—the way we 'do' masculinity or femininity. Gender is also important in the way health services are delivered—from how research is conducted and how medical knowledge is constructed and disseminated, to health policy and planning which shapes the availability of medical care, access to care, and how appropriately it meets the needs of men and women. All of these factors combine at the level of the individual to shape their health experience and their need for care, while that care

itself needs to be planned and delivered in such a way that both men and women are able to benefit.

Key messages

- ◆ Both sex and gender play a part in women's and men's health.
- ◆ Sex or biological factors affect incidence and also survival for various diseases.
- ◆ Gender is socially constructed and affects exposure to risk factors as well as influencing health behaviours.
- ◆ Gender also affects the delivery of healthcare, access to care, and how well care meets the needs of women and men.

Child health

Cynthia Boschi-Pinto, Nigel Rollins,
Bernadette Daelmans, Rajiv Bahl,
Jose Martinez, and Elizabeth Mason

The situation of children in the world

Within the life course, the period of life before attaining adulthood is divided into three age subgroups based on epidemiology and healthcare needs: the first 5 years (*under-5 children*), the next 5 years (*older children*), and the second decade of life (*adolescents*). The first 5 years of life are further subdivided into the neonatal period (the first 28 days of life), infancy (the first year of life), and pre-school years (from 1 to 5 years). This chapter focuses on the health of under-5 children.

The most important indicators of health status of under-5 children relate to their mortality, morbidity, nutrition, growth, and development. Poor health and survival are linked to social and economic development and child mortality is one of the most sensitive barometers of this relationship. An overview of the health situation and inequalities among children in the world is presented in this section.

Mortality in under-5 children

Every year 139 million babies are born in the world, of which nearly 5 million will die before their first birthday and an additional 1.7 million before reaching age 5. The first 12 years of the twenty-first century witnessed a 36 per cent decline in under-5 mortality rates (U5MRs)—from 75 in the year 2000 to 48 per 1000 live births in 2012. Despite the progress made in recent decades, 6.6 million children less than 5 years of age continue to die in a year (United Nations Children's Fund (UNICEF) et al. 2013). This figure is more than twice the number of all individuals dying in the same period from HIV infection or AIDS, malaria, and tuberculosis combined. Over 70 per cent of under-5 deaths occur within the first year of life, but the risk of death is the highest closest to birth; it then decreases over the subsequent days, months, and years.

More than 80 per cent of all under-5 deaths are clustered in just two regions of the world: sub-Saharan Africa and South Asia (Fig. 10.3.1) (World Health Organization (WHO) n.d.). Although the African continent has only 25 per cent of the world's under-5 population, it accounts for 51 per cent of the global under-5 deaths; in contrast, less than 1 per cent of under-5 deaths take place in Europe. It is noteworthy that 50 per cent of all these deaths are concentrated in five countries: India, Nigeria, Democratic Republic of Congo, Pakistan, and China (UNICEF et al. 2013).

Most children eventually die from only a small number of diseases and conditions. Globally, the single most important cause of death among newborn babies is complications due to preterm birth, which claims one-third of newborn lives. Birth asphyxia and sepsis are the second and third major causes of death in this early period of life. Among older children (1–59 months), pneumonia, diarrhoeal disease, and malaria are the leading causes of mortality, accounting together for about 50 per cent of the 3.7 million postneonatal deaths (Liu et al. 2012; World Health Organization 2013).

The so-called epidemiological transition has a complex, dynamic course which reflects changes in demographic, socio-economic, cultural, biological, technological, and environmental domains. As a result, important modifications are seen in the patterns of causes of death that usually shift from acute infectious diseases and deficiency-related conditions to non-communicable diseases (NCDs), leading to a relative increase in conditions such as perinatal causes (prematurity, birth asphyxia, and trauma), congenital abnormalities, and injuries. Of the overall 2.7 million fewer under-5 deaths in 2010, as compared to the year 2000, nearly 60 per cent were due to reductions in deaths caused by pneumonia, measles, and diarrhoeal diseases.

Poverty, low levels of maternal education, and poor quality healthcare are underlying determinants of most under-5 deaths. Levels, trends, and progress in both infant and under-5 mortality are unequally distributed between and within regions and countries. Children in low-income countries are nearly 14 times more likely to die before the age of 5 than children in high-income countries (UNICEF et al. 2013). Sub-Saharan Africa has, in general, the highest burden of global child mortality, accounting for 97 per cent of all under-5 deaths attributable to malaria in the world, 91 per cent of all deaths due to HIV and AIDS, 56 per cent due to diarrhoeal diseases, and more than 47 per cent of deaths due to pneumonia. Further critical inequities are present within countries, where children from the poorest families, living in rural areas, and whose mothers are less educated are those more likely to die.

Morbidity in under-5 children

Because the measurement of morbidity is more complex than that of mortality, information on the distribution of morbidity burden among under-5s is scarce. Despite the limitations of

data, it is known that the main causes of morbidity highly correlate with the major causes of death in under-5 children. In 2010, 120 million episodes of pneumonia occurred in children less than 5 years of age, of which 14 million progressed to severe illness (Fischer Walker et al. 2013). An overall 5.5 per cent risk of long-term major respiratory sequelae from childhood pneumonia in non-hospitalized children has been reported, with a threefold higher risk in hospitalized children (Edmond et al. 2012).

Recent estimates of diarrhoeal disease burden show a median of 2.9 episodes per child per year, with the highest number of annual episodes recorded in the African (449 million annual episodes) and South East Asia (437 million annual episodes) regions (Fischer Walker et al. 2012). An important consequence of persistently high rates of diarrhoea morbidity is a negative effect on child growth and development.

Incidence of both pneumonia and diarrhoea are closely associated with poor home environments, undernutrition, and lack of access to health services. The prevalence of pneumonia and diarrhoea can be more than twice as high among the poorest children as among the richest ones. These differences in reported morbidity within countries are illustrated in Fig. 10.3.2.

Nutrition, growth, and development in under-5 children

The nutritional status of under-5 children is usually assessed through three standard indicators: stunting, wasting, and underweight. A stunted child is a child who falls below minus two standard deviations (-2 SD) from the median height-for-age of the WHO Child Growth Standards (World Health Organization 2006a). Stunting is usually a result of chronic undernutrition or nutritional deprivation over a lengthy period of time. A child is

considered wasted when he/she falls below -2 SD from the median weight-for-height of the WHO Standards. Wasting usually reflects an acute nutritional deficiency, due either to reduced food consumption or acute weight loss during an illness. Finally, a child is said to be underweight if his/her weight falls below -2 SD from the median weight-for-age of the WHO Standards, which can be a result of stunting, wasting or both.

Globally, there were 165 million children under-5 stunted, 52 million wasted, and 101 million underweight in 2011 (UNICEF et al. 2012). The proportion of under-5s who are underweight declined by 36 per cent between 1990 and 2011, bringing the world closer to the target of halving the proportion of underweight children between 1990 and 2015. Poor nutritional status of a child is strongly correlated to his/her vulnerability to diseases, to delayed physical and mental development, and to an increased risk of mortality. As described for morbidity and mortality, underweight is usually associated with inadequate maternal education and low levels in other indicators of well-being.

In contrast, almost 43 million under-5 children in the world are overweight (weight-for-height above 2 SD), a 54 per cent increase from an estimated 28 million in 1990 (UNICEF et al. 2012). Prevalence is highest in high- (8.4 per cent) and upper-middle- (6.4 per cent) income countries, where nearly 17 million children are overweight. Obese children have increased risks of adult obesity, diabetes, liver disease, and poor social and economic performance in later life.

The first years of life provide the greatest opportunities for development. Young children have maximum plasticity of neuronal systems and thus benefit the most from interventions. Nonetheless, they are highly vulnerable to negative effects of poor environments such as increased morbidity, undernutrition, and delays in development. Annually, over 200 million children under 5 years of age have

Fig. 10.3.2 Inequities in reported under-5 suspected pneumonia (a) and diarrhoea (b) morbidity in the 2 weeks preceding the interview by place of residence, wealth quintiles, and mother's education in 11 African countries and five Asian countries.

significantly impaired growth and development, most of whom live in south Asia (Grantham-McGregor et al. 2007).

A child's environment and activities while growing shape their cognitive abilities and general development. Optimal child development is a result of adequate nutrition, prevention, and timely management of illness, care, and stimulation. Malnourished, sick, and disabled children are at particular risk of a poor development. They have more difficulty learning, are less active, and may be less able to receive the attention needed from those who care for them. Effective interventions that impact on child development are available along the life course. They aim to improve maternal health and fetal outcomes, caregiver-child interactions, responsiveness and stimulation through play and communication. Through stimulation and interactions, these interventions intend to enhance the child's ability to learn socially and intellectually and grow physically.

The frequent contact of mothers, their babies, and young infants with health services provides a unique opportunity for these services to actively promote and support early child development.

Addressing health needs of the child in low- and middle-income countries

Children whose environments have limited resources need interventions to protect them against the major causes of mortality and morbidity summarized in the previous section. There are two main types of interventions. The first promote health and prevent specific disease conditions. The second are case management interventions which help reduce severity of illness thereby improving health and survival. Key interventions are reviewed in the following text for each of the major causes of under-5 mortality and summarized in Table 10.3.1.

Newborn conditions

The proportion of under-5 deaths that occur within the first month of life has increased 19 per cent since 1990, because declines in the

neonatal mortality rate have been slower than those in the mortality rate for older children. Improving newborn health and survival requires a continuum of care from pregnancy, childbirth, and the newborn period, into childhood and adolescence. Newborn health interventions can be classified into those relevant for all mothers and newborns, and those relevant only for newborns with conditions that require additional care.

Care for all mothers and newborns

Newborn health and survival requires empowerment (particularly of girls and women) and health promotion through life, which includes nutrition and education, prevention of harmful practices such as female genital mutilation, delay in sexual debut, prevention and treatment of sexually transmitted infections, and support for optimal timing and spacing of pregnancies. Care during pregnancy is important for newborn survival. Interventions of proven benefit for newborn health provided during antenatal care include tetanus immunization, screening for and treatment of syphilis and HIV, prevention and treatment of malaria and calcium supplementation in populations with low dietary calcium intake. Antenatal care provides the basis for continued care during and after childbirth by planning for birth with a skilled attendant and preparing for unforeseen complications, and by helping the family prepare for maternal and newborn care practices, such as early initiation of and exclusive breastfeeding.

Skilled care at childbirth is needed for all women and babies without exception because the complications that may occur during and immediately following childbirth (for both mothers and babies) cannot be predicted and may very rapidly become fatal. This means that skilled childbirth care in first-level health facilities, with the backup of a hospital that can manage complications, should be available 24 hours a day, every day. For a home birth, it is crucial to have access to a skilled attendant and a companion who can stay with the mother and baby for the first 12–24 hours. For a woman and her family who cannot have access to a skilled attendant in a home birth, it is essential to ensure that they have

Table 10.3.1 Summary of key interventions to address major causes of child mortality and morbidity

Important causes of under-5 mortality and morbidity	Preventive interventions	Case management interventions
Newborn conditions: • Preterm birth • Perinatal asphyxia • Neonatal sepsis	<ul style="list-style-type: none"> • Antenatal care • Skilled care during labour and birth • Care at the time of birth (warmth, cord care, and early initiation of breastfeeding) • Care during the first days and weeks after birth (exclusive breastfeeding, warmth, hygienic skin and cord care, and prompt care-seeking for illness) 	<ul style="list-style-type: none"> • Tocolytics and antenatal corticosteroids for preterm labour • Antibiotics for preterm premature rupture of membranes • Additional care of preterm and LBW infants (addressing feeding, warmth, and breathing problems) • Caesarean section or assisted vaginal delivery in case of fetal distress • Resuscitation if unable to breathe after birth • Diagnosis and treatment of neonatal sepsis and local infections
Pneumonia	<ul style="list-style-type: none"> • Immunization against pneumococcus, <i>Haemophilus influenzae</i>, pertussis, diphtheria, and measles • Exclusive breastfeeding up to 6 months; continued breastfeeding with safe and appropriate complementary feeding at least up to 2 years • Reduction in environmental risk factors—e.g. indoor air pollution 	<ul style="list-style-type: none"> • Treatment of pneumonia with amoxicillin • Treatment of severe pneumonia with parenteral antibiotics, oxygen, and other supportive treatment
Diarrhoea	<ul style="list-style-type: none"> • Early and exclusive breastfeeding up to 6 months; continued breastfeeding with safe and appropriate complementary feeding at least up to 2 years • Vitamin A supplementation • Immunization against rotavirus and measles • Water and sanitation, hand washing with soap 	<ul style="list-style-type: none"> • Fluid replacement to prevent dehydration • Zinc treatment for 10–14 days during diarrhoea • Antibiotics for dysentery
Malaria	<ul style="list-style-type: none"> • Vector control • Use of ITNs 	<ul style="list-style-type: none"> • Treatment of non-severe malaria with oral antimalarial drugs recommended for the area • Treatment of severe malaria with parenteral antimalarial drugs
HIV/AIDS	<ul style="list-style-type: none"> • Primary prevention of HIV and of unintended pregnancies in HIV-infected women • ARVs—treatment of pregnant women when indicated, prophylaxis for others • Exclusive breastfeeding with ARVs or replacement feeding for HIV-positive mother • Co-trimoxazole prophylaxis for HIV-exposed and HIV-infected children 	<ul style="list-style-type: none"> • ART for children who are eligible for it
Malnutrition	<ul style="list-style-type: none"> • Early initiation of breastfeeding • Exclusive breastfeeding up to 6 months of age • Continued breastfeeding with safe and appropriate complementary foods up to at least 2 years • Preventing vitamin A, iron, iodine, and zinc deficiency through supplementation, food fortification, or dietary diversification • Community-based screening for severe acute malnutrition using mid-upper arm circumference (MUAC) measurements 	<ul style="list-style-type: none"> • Community-based management of children with severe malnutrition without complications • Hospital management of severely malnourished children with complications

knowledge of maternal and newborn danger signs, and a plan for a clean delivery and early care-seeking if problems arise.

Care for all newborns at the time of birth and during the days and weeks that follow includes several relatively simple and effective interventions that do not require advanced technology (Box 10.3.1). The most critical time to deliver these interventions is immediately after birth. Another important time period is the first 24 hours after birth as a large proportion of maternal and

neonatal deaths occur during this window. Thereafter, at least one additional contact with a health provider within the first week, preferably on the second or third day of life, is required.

Management and care of newborn conditions

Fifteen million premature babies are born every year of which nearly 1 million die due to complications of *preterm birth* (WHO 2012a). Appropriate management of preterm labour can reduce

Box 10.3.1 Basic newborn care at the time of birth and in the days and weeks after birth**Care at the time of birth**

- ◆ Birth in a warm room.
- ◆ Drying the baby thoroughly immediately after birth.
- ◆ Keeping the baby in skin-to-skin contact with the mother.
- ◆ Hygienic cord care.
- ◆ Eye care.
- ◆ Early initiation of breastfeeding as soon as the mother and the baby are ready (usually within the first hour of birth).

Care during the first days and weeks

- ◆ Exclusive breastfeeding.
 - ◆ Keeping the newborn warm.
 - ◆ Hygienic cord and eye care.
 - ◆ Vaccination.
- ◆ Prompt recognition of danger signs (not feeding well, reduced activity, fast or difficult breathing, fever or low body temperature, or convulsions) and care seeking by the family.

mortality and morbidity in neonates. Key interventions include tocolytics to delay birth, and corticosteroids given to the mother during preterm labour to promote lung maturation of the baby. In addition, if there is preterm pre-labour rupture of membranes antibiotics should be given.

Additional care of preterm and low birth weight (LBW) infants is critical for improving newborn survival. Identification of LBW infants within the first hours after birth should be a part of the basic newborn-care package. In settings where birth weight measurement is not feasible, such as for home births, all newborns perceived to be 'small' should receive additional care. These may include one additional contact in the first week and weekly contacts thereafter until the infant is feeding and growing well.

In addition to basic newborn care, LBW infants need more attention for warmth, feeding, hygiene, early detection of infections, and growth monitoring. Kangaroo mother care or skin-to-skin care is the best way to keep them warm and to encourage breastfeeding. Mothers who cannot breastfeed directly should be taught to express breast milk and to feed from a cup. Much of this additional care can be provided at home and in first-level health facilities. However, care for babies weighing less than 1500 g, who have difficulty feeding or breathing due to lung immaturity, is best provided in a hospital.

Perinatal asphyxia is responsible for 10 per cent of all under-5 deaths. The most important intervention for preventing deaths and severe morbidity due to perinatal asphyxia is monitoring of progress in labour and maternal and fetal well-being during labour using a partograph. Fetal monitoring should be conducted during labour, and should be associated with prompt and appropriate action if fetal distress is detected. When fetal distress is suspected, assisted vaginal or Caesarean birth may be needed which requires functional referral mechanisms. The second key intervention for prevention of asphyxia-related mortality and

morbidity is neonatal resuscitation. Given the likelihood/possibility of this, all birth attendants should be skilled and equipped to perform neonatal resuscitation, which includes positive pressure ventilation with a self-inflating bag and mask using room air, in addition to thorough drying and stimulation.

Management of *newborn infections* in a swift and appropriate manner can substantially reduce neonatal mortality. It is therefore important to have community- and health-facility-based activities which support families in identifying the danger signs and seeking timely and appropriate care. Newborns with severe infections should receive parenteral antibiotics, along with intravenous fluids or alternative feeding methods and other supportive therapy such as oxygen in a hospital. Research studies are currently underway to determine if a proportion of these children can be safely managed at home using intramuscular or oral antibiotics.

Acute respiratory infections

Acute respiratory infections (ARIs), particularly pneumonia, are the leading cause of under-5 mortality as they are responsible for 18 per cent of all child deaths worldwide. Interventions to control ARIs can be divided into preventive interventions such as immunization against specific pathogens, improvements in nutrition, safer environments, and case management interventions.

Widespread use of vaccines against pneumococcus, *Haemophilus influenzae* (Hib), pertussis, diphtheria, influenza, and measles has the potential to substantially reduce the incidence of ARIs in children in low- and middle-income countries. Two particularly important vaccines are those against *Pneumococcus* and Hib, pathogens responsible for about half of all cases of pneumonia.

Two types of pneumococcal vaccines are currently licensed for use: a polysaccharide vaccine effective against 23 different strains of *Pneumococcus* and two different formulations of protein-conjugated vaccines (PCVs) effective against ten or 13 serotypes of pneumococcus, respectively. The serotypes included in these vaccines account for the majority of serious pneumococcal disease in children worldwide (Johnson et al. 2010). Use of these vaccines in countries in North America and Europe has seen declines in rates of invasive pneumococcal disease in children and also in pneumonia hospitalization (Grijalva et al. 2007; Jardine et al. 2010; Pilishvili et al. 2010; Miller et al. 2011). Studies to document the impact of PCVs in low-income countries are ongoing. PCVs are increasingly available in low-income, high-mortality countries, but gaps in vaccine uptake within countries could reduce their impact.

The use of Hib conjugate vaccines in developed countries has resulted in the virtual elimination of invasive Hib disease (meningitis and bacteraemic pneumonia) because of immunity in vaccinated children and a herd effect in those not vaccinated. There are several Hib conjugate vaccines available, all of which are effective when given in early infancy and have virtually no side effects. The success of these vaccines is seen in most low-income countries which have introduced Hib vaccines.

Vaccination should be seen as complementary to other strategies for pneumonia control, such as improved care-seeking and case management, better nutrition (including exclusive breastfeeding for the first 6 months of life), and measures to reduce indoor air pollution. Results from two meta-analyses of published studies showed that young children exposed to smoke from use of

household biomass fuel had a rate of acute lower respiratory infection twice that of children not exposed (Smith et al. 2004; Dherani et al. 2008). In a trial in Guatemala, environmental interventions to reduce exposure to indoor air pollution have been shown to reduce the incidence of severe respiratory infections in children (Smith et al. 2011).

Clinical guidelines for ARI case management rely on two simple clinical signs: fast breathing and lower chest wall in-drawing to identify children with ARI who need antibiotic therapy (WHO 2012b). Fast breathing detects about 85 per cent of pneumonia patients. The specificity of fast breathing is 70–80 per cent, which means that 20–30 per cent of children with ARI who do not need antibiotics will receive them. However, the use of this sign renders decision-making by first-level health workers simple thereby increasing the proportion of children with pneumonia who receive antibiotics. Chest in-drawing is the inward movement of the lower chest wall when a child breathes in. Children with chest wall in-drawing who do not have any of the danger signs can be successfully treated with oral amoxicillin (Hazir et al. 2008; Addo-Yobo et al. 2011; Bari et al. 2011; Soofi et al. 2012).

Children with audible stridor when calm and any general danger signs such as lethargy or unconsciousness and inability to feed should be managed in a hospital with parenteral antibiotics and supportive care. Oxygen should be used in children who are unable to feed or drink, are drowsy or lethargic, or have central cyanosis, head nodding, respiratory rate of 70 breaths/minute or more, or severe chest wall in-drawing. Pulse oximetry should preferably be used to assess hypoxaemia (WHO 2012b).

Diarrhoea

Diarrhoea remains one of the leading causes of death among under-5 children in low- and middle-income countries. Strategies for the control of diarrhoeal diseases have remained substantially unchanged since the early 1980s. A package of proven prevention and treatment measures is available that, if taken to scale, will lead to a significant reduction in the burden of diarrhoeal disease. It consists of a seven-point plan for diarrhoea control and includes promotion of early and exclusive breastfeeding, vitamin A supplementation, rotavirus and measles vaccination, promotion of hand washing with soap and improved water supply, promotion of community-wide sanitation, fluid replacement to prevent rehydration, and zinc treatment (UNICEF and WHO 2009).

Exclusively breastfed children under 6 months of age are ten times less likely to die of diarrhoea than non-breastfed infants (Lamberti et al. 2011). This is because breast milk contains antimicrobial factors in addition to eliminating the intake of potentially contaminated food and water. Safe and appropriate complementary foods introduced at 6 months of age and continued breastfeeding for at least up to 2 years can improve nutritional status of infants and young children helping to prevent nutritional deterioration, impaired immune function, and greater susceptibility to infection sometimes caused by sequential episodes of diarrhoea.

Rotavirus is the most common cause of diarrhoea worldwide, accounting for at least one-third of severe and potentially fatal watery diarrhoea episodes, primarily in low- and middle-income countries where an estimated 450,000 vaccine-preventable rotavirus deaths occurred in 2008 (Tate et al. 2012). Two licensed rotavirus vaccines (85–98 per cent protective efficacy against severe diarrhoea in high- and middle-income and 50–70 per cent in

low-income countries), derived from human or bovine rotavirus (Armah et al. 2010; Zaman et al. 2010), have been introduced into national immunization programmes in over 35 countries worldwide. Candidate vaccines are undergoing field trials in low- and middle-income countries. In countries where diarrhoeal deaths account for at least 10 per cent of mortality among children aged less than 5 years, the introduction of the vaccine is strongly recommended (WHO 2009).

Human faeces are the primary source of diarrhoeal pathogens. Poor sanitation, lack of accessible clean water, and inadequate personal and domestic hygiene are responsible for an estimated 88 per cent of diarrhoeal cases everywhere (WHO 2007). Hand washing with soap reduces the risk of diarrhoea by an average of 48 per cent (Munos et al. 2010), and is best when undertaken as part of a package of behaviour-change interventions such as treating and safely storing drinking water at the point of use. However, the required behaviour change is complex and often difficult to sustain. Thus, significant resources should also be directed towards extending and sustaining water, sanitation, and hygiene services at community level.

Most deaths from diarrhoea occur because of dehydration associated with acute diarrhoea, and because of dysentery (bloody diarrhoea). Management of diarrhoea includes:

- ◆ Treating dehydration with oral rehydration salts (ORS) solution, or with an intravenous electrolyte solution in cases of severe dehydration.
- ◆ Providing children with 20 mg per day of zinc for 10–14 days.
- ◆ Continuing or increasing breastfeeding during and increasing feeding after the diarrhoeal episode.
- ◆ Using antibiotics only when appropriate (i.e. bloody diarrhoea) and not administering antidiarrhoeal drugs

Use of oral rehydration solution reduces diarrhoea-specific mortality by 69 per cent (Munos et al. 2010). Two noteworthy advances in the management of acute diarrhoea are: newly formulated ORS containing lower concentrations of glucose and salts, and zinc supplementation. ORS formulation has proved safe and effective in the prevention and treatment of dehydration. However, mothers' and health workers' acceptance of standard ORS has been sub-optimal because watery stools persist and the duration of diarrhoea is not reduced. Efforts over the past decades have led to the development of a new ORS formulation. Compared with standard ORS, this lower sodium and glucose ORS reduces stool output, vomiting, and the need for intravenous fluids. The new ORS is safe and effective in both non-cholera diarrhoea and cholera in children and adults. WHO and UNICEF now recommend the use of ORS containing 75 meq of sodium and 75 mmol of glucose per litre (total osmolarity of 245 milliosmol per litre) everywhere (WHO 2005a). In addition to fluid replacement, children with diarrhoea should continue to be fed during the episode. Food intake supports fluid absorption and helps maintain nutritional status and ability to fight infection.

A recent review of relevant clinical trials indicates that zinc supplements given during an episode of acute diarrhoea reduce the duration, the risk of hospitalization, and the incidence of future episodes of diarrhoea (Fischer Walker and Black 2010). Studies from India show that including zinc in the management of acute diarrhoea has some programmatically important effects

such as the reduction of hospital admissions for diarrhoeal disease (Mazumder et al. 2010). The addition of zinc to ORS in the treatment of diarrhoea has also increased the use-rates of ORS and reduced prescription of drugs of unknown identity and antibiotics (Bhandari et al. 2008). All children with acute diarrhoea should be given zinc supplements for 10–14 days during and after diarrhoea (10 mg per day for infants younger than 6 months of age and 20 mg per day for those over 6 months).

Dysentery—an inflammatory disorder of the lower intestinal tract, resulting in pain, fever, and severe diarrhoea, often accompanied by the passage of blood and mucus—is a major cause of diarrhoeal morbidity and mortality. *Shigella* is the most common and severe cause of bloody diarrhoea. The primary treatment for shigellosis is the use of antimicrobials which can decrease mortality attributable to dysentery by more than 99 per cent (Traa et al. 2010). The choice of effective, safe, oral, and inexpensive drugs for use in low- and middle-income countries has become problematic because of the increasing prevalence of antimicrobial drug resistance to several commonly used antibiotics. Ciprofloxacin is the current treatment drug of choice due to its effectiveness, safety, ease of administration by the oral route, short course, and low cost. However, ciprofloxacin-resistant strains are already appearing and this has made development of a vaccine for *Shigella* a high priority. For severe cholera cases, WHO recommends the use of oral antibiotics to which strains of *Vibrio cholerae* in the area are known to be sensitive; possible choices are: tetracycline, doxycycline, co-trimoxazole, erythromycin, and chloramphenicol. Antibiotic management of cholera results in a 63 per cent reduction in rates of clinical failure and a 75 per cent reduction in rates of bacteriological failure (Das et al. 2013).

Malaria

Malaria accounts for 7 per cent of child deaths worldwide. Nearly 500,000 children under age 5 are killed by malaria every year, 97 per cent of them in sub-Saharan Africa. Together with pneumonia and diarrhoea, malaria claimed the most lives among children 1–59 months of age (Liu et al. 2012). Chapter 8.15 on malaria describes malaria interventions in greater detail.

Vector control remains the most generally effective measure to prevent malaria transmission in all ages. For example insecticide-treated nets (ITNs) have been shown to be particularly effective in reducing uncomplicated malaria incidence and parasite infection prevalence in young children (Eisele et al. 2010).

Prompt parasitological confirmation by microscopy or alternatively by rapid diagnostic tests in all patients suspected of malaria should happen before treatment is started. Treatment solely on the basis of clinical suspicion should only be considered when a parasitological diagnosis is inaccessible. Once diagnosed, the child should be treated early with a safe and effective antimalarial medicine as delaying treatment could result in progression to severe disease, which is associated with a high case-fatality rate.

Malaria case management has been greatly affected by the emergence and spread of chloroquine and sulfadoxine/pyrimethamine resistance. To counter the threat of drug resistance of *Plasmodium falciparum* to monotherapies and to improve treatment outcomes, use of artemisinin-based combination antimalarials is recommended for treatment of uncomplicated malaria (WHO 2010a). In areas with poor access to health facilities, early recognition,

prompt, and appropriate treatment require treatment in the home or community.

HIV and AIDS

In 2011, 3.4 million children under the age of 15 were living with HIV, 92 per cent of them in sub-Saharan Africa. Every day about 900 children are newly infected. While HIV/AIDS accounts for about 2 per cent of under-5 deaths globally (Liu et al. 2012; WHO 2013), in southern Africa it is responsible for about 26 per cent of these child deaths. In countries such as South Africa, where general HIV prevalence is among the highest in the world, the estimated proportion of child death due to HIV/AIDS reached 28 per cent in 2010. Although the proportional mortality due to HIV/AIDS among under-5s remains unacceptably high in some African countries, it has declined significantly in the last decade due to scaling-up of interventions to prevent infections in children. Diagnosis of HIV-infection in children less than 18 months is based on demonstrating the presence of HIV DNA through polymerase chain reaction testing and beyond this age by detecting antibodies to HIV through an enzyme-linked immunosorbent assay. This is because maternal antibodies to HIV can pass through the placenta and remain present in HIV-exposed but uninfected children until the age of 18 months.

Over 90 per cent of HIV-infected children are infected through mother-to-child transmission (MTCT), which may occur during pregnancy, birth, or through breastfeeding. Without any interventions, the risk of transmission is between 20 and 45 per cent, but this can be reduced to less than 2 per cent with a package of evidence-based interventions (WHO 2010b). Antiretroviral (ARV) drug interventions given to pregnant HIV-infected women are very effective at preventing peripartum MTCT and also protect the health and survival of mothers (WHO 2010b).

Postnatal ARV interventions are now recommended to reduce the risk of HIV transmission through breastfeeding. These can be given either to the mother (Shapiro et al. 2010; Kesho Bora Study Group 2011) or to the infant (Coovadia et al. 2012). The effectiveness of these interventions has transformed the landscape in which programmatic and individual decisions about feeding practices in the context of HIV can be made. Based on the strength of this evidence and programmatic considerations, national authorities are advised to promote and support one infant feeding practice for HIV-infected mothers, namely, either breastfeeding with ARVs or to avoid all breastfeeding and use replacement feeds (WHO 2010b). Achieving high coverage of these interventions in resource-limited countries has, however, been challenging. Access to CD4 counts to establish which pregnant women are eligible for lifelong ARV treatment and who should receive prophylaxis has been a barrier in many settings to effective scaling up. It is also recognized that women in high-prevalence countries are likely to have repeated pregnancies that would each involve ARV interventions, either prophylaxis or treatment. For these reasons, and also to protect the health of mothers, several national programmes have opted to start all pregnant HIV-infected women on lifelong treatment (Centers for Disease Control and Prevention 2013). Whether all HIV-infected pregnant women will want to start lifelong treatment and how best to support women to remain in care and achieve high rates of adherence remain important unanswered questions.

In settings where diarrhoea, pneumonia, and malnutrition continue to be significant causes of child mortality, breastfeeding is likely to give HIV-exposed infants the greatest chance of HIV-free survival (Kagaayi et al. 2008; Peltier et al. 2009). To achieve this, mothers known to be HIV-infected should be provided with either lifelong ARV therapy or ARV prophylaxis interventions to reduce HIV transmission through breastfeeding. These mothers should therefore exclusively breastfeed their infants for the first 6 months of life, introducing appropriate complementary foods thereafter, and continue breastfeeding for the first 12 months of life. Breastfeeding should then only stop once a nutritionally adequate and safe diet without breast milk can be provided.

In countries where infectious diseases and malnutrition do not contribute significantly to child mortality, mothers known to be HIV-infected may be advised to give their infants replacement feeds and avoid all breastfeeding. Commercial infant formula milk should be given as the replacement feed to these HIV-uninfected infants only when the following specific conditions are met:

- ◆ Safe water and sanitation are assured at the household level and in the community; and
- ◆ The mother or other caregiver can reliably provide sufficient infant formula milk to support normal growth and development of the infant; and
- ◆ The mother or caregiver can prepare it cleanly and frequently enough so that it is safe and carries a low risk of diarrhoea and malnutrition; and
- ◆ The mother or caregiver can, in the first 6 months, exclusively give infant formula milk; and
- ◆ The family is supportive of this practice; and
- ◆ The mother or caregiver can access healthcare that offers comprehensive child health services.

Irrespective of the common causes of death, when infants and young children are known to be HIV-infected, mothers are strongly encouraged to exclusively breastfeed for the first 6 months of life and continue breastfeeding as per the recommendations for the general population that is up to 2 years or beyond.

HIV-exposed or HIV-infected children may acquire a serious life-threatening form of pneumonia caused by *Pneumocystis jirovecii* (previously known as *carinii*), which often occurs before their HIV status has been confirmed. Co-trimoxazole, a fixed-dose combination of sulfamethoxazole and trimethoprim, is a broad-spectrum antimicrobial agent that targets a range of aerobic Gram-positive and Gram-negative organisms, fungi, and protozoa. The drug is widely available in both syrup and solid formulations at low cost in most places, including resource-limited settings. Regular prophylaxis with trimethoprim-sulfamethoxazole (co-trimoxazole) provides a simple, inexpensive, and effective strategy to reduce the risk of this infection, and has been shown to reduce mortality of HIV-infected children by up to 40 per cent even in the absence of ART (Chintu et al. 2004). Co-trimoxazole prophylaxis may also reduce the risk of malaria-related mortality in both HIV-infected and exposed children (Sandison et al. 2011) while it is unclear whether this would be effective in other children as well. Because of difficulty in diagnosing HIV infection in infants, co-trimoxazole prophylaxis is recommended for all HIV-exposed children born to mothers living with HIV starting

at 4–6 weeks after birth and continuing until HIV infection has been excluded and the infant is no longer at risk of acquiring HIV through breastfeeding (Newell et al. 2004).

HIV-exposed and HIV-infected children should receive all vaccines as early in life as possible, except Bacillus Calmette–Guérin (BCG) and yellow fever vaccines. In asymptomatic children, the decision to give late BCG should be based on the local risk of tuberculosis. Infants with symptomatic HIV infection should not receive yellow fever vaccines.

Antiretroviral therapy (ART), which means ARV drugs given in the correct way and with adherence, can substantially improve survival of HIV-infected children as without treatment 50 per cent of infected children die before the age of 2 (WHO 2006c). The availability of simple fixed-dose combinations of ARV drugs and other formulations such as ‘sprinkles’ make earlier initiation and adherence to treatment by children more feasible. Understanding, however, the particular needs of adolescents infected with HIV such as access to adolescent-friendly sexual and reproductive health services are increasingly recognized as priorities. ‘Treatment 2.0’ is a WHO/UNAIDS initiative that aims to catalyse the next phase of HIV treatment scale-up through promoting innovation and efficiency gains (WHO 2011a). It will help countries to reach and sustain universal access to treatment, and capitalize on the preventive benefit of ART through focused work in five priority areas: optimize drug regimens, provide point of care diagnosis, reduce costs, adapt delivery systems, and mobilize communities.

Malnutrition

Malnourished children have substantially higher risks of death from common childhood illness such as diarrhoea, pneumonia, and malaria. Nutrition-related factors directly or indirectly contribute to 45 per cent of deaths in children under 5 years of age (Black et al. 2013).

Interventions to prevent malnutrition include promotion of optimal feeding of infants and young children, prevention and treatment of illness, and amelioration of micronutrient deficiencies in the diet. Early initiation of breastfeeding, exclusive breastfeeding up to 6 months of age, and continued breastfeeding along with complementary foods up to at least 2 years of age are key interventions to combat undernutrition. Early initiation of breastfeeding, ideally within the first hour after birth, is associated with a reduced risk of neonatal mortality (Edmond et al. 2006) and exclusive breastfeeding during the first 6 months of life is associated with about a tenfold lower risk of death due to any cause than not breastfeeding at all, and a two- to threefold lower risk of death than partial breastfeeding (Bahl et al. 2003). Continued breastfeeding into the second year of life also reduces the risk of child mortality and malnutrition. Multiple approaches exist to promote breastfeeding through health facility and community programmes, including health education, professional support, lay support, and mass media campaigns. Safe and appropriate complementary feeding started at 6 months of age can reduce the prevalence of malnutrition and contribute to reduced mortality. Promotion of safe and appropriate complementary feeding improved weight-for-age and height-for-age gains by 0.24–0.87 SD in pilot studies (WHO 1998). Effects of this magnitude if reproduced on a large scale could translate into tangible reductions in rates of malnutrition and the mortality attributable to it.

To improve the nutritional status of children and prevent them from becoming severely malnourished, the dietary management of moderate malnutrition should be based on optimal use of locally available nutrient-dense foods. Intake of nutrients present in inadequate amounts in the habitual diet can be increased through a number of approaches, including dietary diversification and fortification of certain staple foods with vitamins and minerals. In situations of food shortage, or where some nutrients are not sufficiently available through local foods, specially formulated supplementary foods are usually required to complement the regular diet; these supplementary foods are not intended for prevention of malnutrition (WHO 2012d).

Common micronutrient deficiencies such as those of vitamin A, iron, iodine, and zinc, both at clinical and subclinical levels, contribute to illness and mortality in children. Approaches to prevent these deficiencies include supplementation (WHO 2011c, 2011c, 2011d), food fortification, and dietary diversification (Pan American Health Organization and WHO 2003; WHO 2005b).

Severe acute malnutrition in children 6–59 months of age is defined as weight-for-height criterion less than -3 SD of the WHO Growth Standards median, or mid-upper-arm circumference (MUAC) less than 115 mm, or the presence of bilateral oedema. For infants less than 6 months, there is no agreed cut-off value for MUAC.

Children with severe malnutrition should first be assessed with a full clinical examination to confirm whether they have medical complications and whether they have an appetite. Children who pass the appetite test and are clinically well and alert should be treated as outpatients whilst those with medical complications or who fail the appetite test should be treated as inpatients. Young infants less than 6 months with severe acute malnutrition who are found to have recent weight loss or ineffective feeding should always be admitted.

Case management is generally organized in two phases: the stabilization phase (usually 3–5 days) when children with severe acute malnutrition who have complications require careful evaluation and treatment of infections, electrolyte imbalance, hypoglycaemia, and hypothermia; and the rehabilitation phase (usually 4–6 weeks) consisting of the provision of nutritional and psychosocial support to achieve full nutritional recovery. Therapeutic feeding should start early in the stabilization phase and include giving a low-protein milk-based formula diet with additional vitamins and minerals such as the WHO-recommended F-75 (75 kcal/100 mL). In the rehabilitation phase, a milk formula with higher protein and energy content such as F-100 should be given and additional iron is needed to address deficiencies. Ready-to-use therapeutic foods (RUTFs) have replaced liquid F-100 in a variety of settings because they do not contain free water and can therefore be used without risk of bacterial contamination. Most RUTFs are lipid-based pastes combining milk powder, electrolytes, and micronutrients to meet recommended nutritional values and offer the malnourished child the same nutrient intake as F-100 when consumed in isoenergetic amounts. RUTFs also contain 10–14 mg/100 g of iron, therefore no additional intake of iron is necessary.

In combination with community-based screening, RUTFs are highly effective in the treatment of severe acute malnutrition in children 6–59 months of age without complications (Collins et al.

2006; WHO et al. 2007). These children can be managed in the community without the risks of nosocomial infections or any other disruptions regarding hospital care to the family.

In children less than 6 months of age who have severe acute malnutrition, care should focus on managing sepsis and other underlying complications and on re-establishing breastfeeding where this has been ineffective. They need milk-based diets and should generally be managed in a hospital, where their mothers can obtain additional support.

Strengthening of child health services

It is not possible to scale-up child health interventions effectively without dealing with the challenges that affect health systems in many low-income countries. Programmes to address newborn and child health are implemented through ‘complex public and private organizations that rely on systems to provide medicines, finance health services, assure quality and efficiency of care, manage the health workforce, and generate information needed for effective operational decisions’ (Countdown Working Group on Health Policy and Health Systems et al. 2008).

Key input components to the health system (Fig. 10.3.3) include evidence-based policies, adequate and skilled health workforce, and sufficient health financing—critical determinants of access, quality, and demand for effective interventions. Service delivery, together with medical products and technologies, reflect the immediate outputs of the health system, that is, the availability and distribution of care (WHO 2010c).

Governance

Supportive laws and policies are a prerequisite for strengthening the health sector’s capacity to respond to the needs of the population. Examples of evidence-based policies that have a specific bearing on child health and that are currently being promoted in countries to tackle the burden of ill health and excess mortality are (WHO 2012c):

- ◆ Maternity protection in accordance with the International Labour Organization Convention 183.
- ◆ Policy on midwives authorized to administer a core set of life-saving interventions.
- ◆ Policy on postnatal home visits in the first week of life.
- ◆ The International Code of Marketing of Breast-milk Substitutes.
- ◆ Policy on community treatment of pneumonia with antibiotics.
- ◆ Policy on low osmolality ORS and zinc.
- ◆ Policy on rotavirus and pneumococcal vaccines.

In order to facilitate the adoption of these policies in countries, advocacy and policy dialogue with a wide range of stakeholders is usually required. Some policies gain wide adherence rapidly while others lag behind. For example, among the 75 countries with the highest burden of maternal and child deaths, the number of those with a policy allowing community health workers to treat pneumonia has more than doubled from 18 to 38 between 2008 and 2012. In contrast, only 23 of these high-burden countries have adopted legislation on the International Code of Marketing of Breast-milk Substitutes, which was almost unanimously endorsed by the member states of the WHO in 1981.

Critical subsystems

Economic hardship and financial crises have eroded the health sector in many countries over the past two decades. Many national health systems are in disarray, with a deteriorating infrastructure and a public health sector subject to the resource restrictions consequent to structural adjustment and macroeconomic ceilings. As a result, human resources working in the health sector have been destabilized and undermined. In many countries, households spend considerable amounts on healthcare and out-of-pocket expenditures for health services can be between two and three times greater than the total health expenditure by governments and donors.

The higher the proportion of user payments in the total finance for health, the greater the relative share of financial burden on the poor and thus they are unable to afford necessary healthcare. Household expenditure surveys suggest that more than 150 million individuals globally face severe financial hardship each year due to healthcare costs. Prepayment systems involve advance collection of funds through tax-based insurance or social health insurance schemes and should be used to promote fair access to health services. Both provide financial risk protection and

promote equity through prepayment of healthcare costs and pooling of health risks. Out-of-pocket expenditures should be gradually converted into prepayment schemes, including community finance programmes. Unfortunately, rectifying the current state of healthcare services could take many years.

Health workers are 'all people engaged in actions whose primary intent is to enhance health'. This includes health service providers such as doctors, nurses, midwives, pharmacists and community health workers. It also includes health management and support workers who dedicate all or part of their time to improving health' (WHO 2006d). The availability of a competent workforce is key to successfully delivering child healthcare and services. Critical shortages, inadequate skill mix, and uneven geographical distribution of the health workforce are major barriers to achieving globally set child health goals and targets. The minimum threshold necessary to deliver essential maternal and child health services is estimated as 23 doctors, nurses, and midwives per 10,000 population. Countries that fall below this threshold struggle to provide skilled care at birth to significant numbers of pregnant women, as well as emergency and specialized services for newborns and young children, impacting the burden of women and children mortality

directly. Among countries categorized as low-income economies by the World Bank, only five met this minimum threshold in 2010.

In almost all countries, a poor mix of the types of health workers and their range of individual skills, combined with a shortage of qualified health workers in remote and rural areas, impedes access by women and children to life-saving interventions and services. To address these challenges, countries are exploring and applying different solutions. Community-based health workers can provide a number of life-saving child health services, such as immunizations and management of non-severe pneumonia. As a result, governments in various countries are instituting new cadres of community health workers or upgrading the skills of existing community resource persons to deliver an essential package of health services that include child health interventions. Similarly, midwifery personnel are enabled to perform life-saving interventions such as resuscitation of the asphyxiated baby. The process of sharing tasks at various levels of service delivery sometimes referred to as task-shifting or task delegation is being investigated and applied in a number of countries.

Comprehensive and long-term health workforce development strategies and approaches that respond to country and situation needs must be in place to ensure skilled, motivated, and supported health workers are at the right place at the right time delivering the right interventions to children who need them.

Service delivery

Despite the fact that effective interventions exist against all major conditions from which children die, the coverage of these interventions generally remains low. The key to achievement of substantial child mortality reduction is quality universal coverage of the interventions previously described.

Before the mid 1990s, child health programmes in low- and middle-income countries focused on immunization, control of diarrhoeal diseases, ARIs, and nutrition. Their implementation led to reduction in under-5 mortality in many countries, but this approach encountered limitations. The narrow focus on single interventions has failed to consider the child in a holistic manner, leading to many missed opportunities for care in contacts with a health practitioner. It was also difficult to resolve upstream health-system constraints such as management or human resource policies using this approach. Solving these problems involves ensuring access to an integrated package of interventions that are organized around the continuum of care. It also means that care should span across the home, community, health centre, and hospital. The advantages of delivering interventions as packages include the following:

- ◆ Many interventions go naturally together because they are delivered by the same person at the same time.
- ◆ Packaging is more cost-effective in terms of training, implementation, and supervision.
- ◆ Packaging meets the needs of the individual caregiver and the child much better than isolated and uncoordinated single-intervention delivery, thus reinforcing the continuum of care.

Potential obstacles to packaging of interventions may be related to policy, programmes, and the organizational structure of ministries and health services. For example, managers responsible

for single issue-focused programmes may feel that packaging their interventions with other maternal and child health services lessens their delivery efficiency. Another concern about packaging interventions is that vulnerable groups may not get any of the interventions if insufficient attention is given to equitable delivery of the package.

Integrated management of childhood illness

Integrated management of childhood illness (IMCI) was developed as an integrated delivery approach to managing common childhood diseases based on the principles of primary health-care (PHC) as set out in the Alma Ata Declaration. This approach focuses holistically on the child and includes strengthening health workers' skills at the first level of the health system for appropriate treatment of common diseases, promotion of proper nutrition, and reduction of missed opportunities for immunization. Further, it includes strengthening the provision of essential drugs and supplies, supervision, and referral links. Finally, the promotion of key family and community practices contributes to the remaining components of PHC as related to children.

IMCI has improved health worker performance, drug availability, rational use of drugs, organization of work at health facilities, use of referral notes, and maintenance of records at district level (Gouws et al. 2004), and has increased health facility utilization (Arifeen et al. 2004). In India, implementation of the Integrated Management of Neonatal and Childhood Illness (IMNCI) programme resulted in substantial improvement of neonatal survival in those babies born at home as well as in improvement of general infant survival (Bhandari et al. 2012).

International efforts to accelerate progress in child survival

In September 2000, at the United Nations (UN) Millennium Summit, 189 national leaders endorsed 'The Millennium Declaration', aimed at promoting poverty elimination, which includes the development of education, promotion of and respect for human rights and equality, and improvement of the environment. The declaration was a commitment to attain eight specific goals by 2015 and to accomplish the aims established. While all the *Millennium Development Goals* (MDGs) are relevant to child health, MDGs 1, 4, 5, and 6 are directly related to child survival (see Box 10.3.2). The fourth MDG has the explicit target of 'reducing by two-thirds, between 1990 and 2015, the under-5 mortality rate' (UN 2000). Based on an U5MR of 90 per 1000 live births in 1990, the global target is to reach a mortality rate of 30 per 1000 live births by 2015.

Overall, substantial progress has been made towards achieving MDG 4. Reductions in under-5 mortality in many regions and countries have diminished the global number of under-5 deaths by more than 47 per cent, from 12.6 million in 1990 to an estimated 6.6 million in 2012. The most pronounced falls in U5MRs have occurred in four regions: Latin America and the Caribbean; East Asia and the Pacific; Central and Eastern Europe and the Commonwealth of Independent States (CEE/CIS); and the Middle East and North Africa. All have more than halved their regional rates of under-5 mortality since 1990. The corresponding decline for South Asia was 53 per cent, which in absolute terms translates into 2.6 million fewer under-5 deaths in 2012 than in 1990 — by

Box 10.3.2 The Millennium Development Goals

- ◆ Goal 1: eradicate extreme poverty and hunger.
- ◆ Goal 2: achieve universal primary education.
- ◆ Goal 3: promote gender equality and empower women.
- ◆ Goal 4: reduce child mortality.
- ◆ Goal 5: improve maternal health.
- ◆ Goal 6: combat HIV/AIDS, malaria and other diseases.
- ◆ Goal 7: ensure environmental sustainability.
- ◆ Goal 8: develop a global partnership for development.

far the highest absolute reduction among all regions. Sub-Saharan Africa, though lagging behind the other regions, has registered a 45 per cent decline in the U5MR (UNICEF et al. 2013).

Countries that have rapidly increased coverage for multiple interventions across the continuum of care have accelerated child survival. Their success can mainly be attributed to improvements in service quality—bringing them closer to home and expanding access to essential care.

In September 2010, the Secretary-General of the UN launched the *Global Strategy for Women's and Children's Health* (Partnership for Maternal, Newborn & Child Health 2010). The main goal of the 'Global Strategy' is to save the lives of 16 million women and children by 2015 and accelerate progress to achieve MDGs 4 and 5. The strategy has helped catalyse new attention and investment to some of the most frequent causes of women's and children's mortality. In response to the UN Global Strategy, WHO co-chaired the Commission on Information and Accountability, which delivered a report (WHO 2011e) with ten recommendations on accountability towards the 'Global Strategy'. The ten recommendations are categorized under the headings: better information for better results, better tracking of resources, and better oversight of results and resources—nationally and globally.

Other recent global initiatives and events are tackling different aspects of implementing the 'Global Strategy', including the Child Survival Call to Action, The Family Planning Summit, and the UN Commission on Life-Saving Commodities for Women and Children. To accelerate progress and achieve improved health outcomes for all children, it is important to ensure universal access to good-quality basic care, clean water, sanitation, and other social sector services such as education. This also includes creating the national legal, policy, and budget frameworks to promote the realization of children's rights to these services.

Child rights

Efforts to ensure effective accountability for children's health are further enhanced by the recognition that availability of and access to health information and services for children and their caregivers are basic human rights. Recognition of need for legal entitlements of every child, regardless of his/her status or situation, elevates associated responsibilities and political commitments to

Box 10.3.3 UN Convention on the Rights of the Child—Article 24

1. States Parties recognize the right of the child to the enjoyment of the highest attainable standard of health and to facilities for the treatment of illness and rehabilitation of health. States Parties shall strive to ensure that no child is deprived of his or her right of access to such health care services.
2. States Parties shall pursue full implementation of this right and, in particular, shall take appropriate measures:
 - (a) To diminish infant and child mortality;
 - (b) To ensure the provision of necessary medical assistance and health care to all children with emphasis on the development of primary care;
 - (c) To combat disease and malnutrition, including within the framework of primary health care, through, inter alia, the application of readily available technology and through the provision of adequate nutritious foods and clean drinking-water, taking into consideration the dangers and risks of environmental pollution;
 - (d) To ensure appropriate pre-natal and post-natal health care for mothers;
 - (e) To ensure that all segments of society, in particular parents and children, are informed, have access to education and are supported in the use of basic knowledge of child health and nutrition, the advantages of breastfeeding, hygiene and environmental sanitation and the prevention of accidents;
 - (f) To develop preventive health care, guidance for parents and family planning education and services.
3. States Parties shall take all effective and appropriate measures with a view to abolishing traditional practices prejudicial to the health of children.
4. States Parties undertake to promote and encourage international co-operation with a view to achieving progressively the full realization of the right recognized in the present article. In this regard, particular account shall be taken of the needs of developing countries.

legal obligations. This paradigm shift thus enables the establishment of not merely a normative but indeed legal foundation for addressing the health needs of children.

The UN Convention on the Rights of the Child (CRC), adopted in 1989 and ratified by all but two UN Member States, is the principal legal instrument for the protection of children's well-being, and outlines the core obligations of States in relation to children's health. Article 24 directly addresses the child's right to health and healthcare (Box 10.3.3), while other provisions refer to the many underlying determinants of children's health. The CRC thus provides a valuable holistic blueprint of all essential needs and legal entitlements of children needed to ensure their survival, health, and optimal development.

Conclusion

ARIs, diarrhoea, malaria, measles, and HIV are the main causes of illness and death in children aged 28 days to 5 years. Among newborn babies, most deaths are due to prematurity, birth asphyxia, and infections. Undernutrition is associated with 45 per cent of all under-5 deaths. Despite the substantial progress made in reducing under-5 mortality, 6.6 million children under 5 still die each year.

Poor health and survival are linked to social and economic disadvantages. Child deaths are unequally distributed in the world. Within countries, child morbidity and mortality tend to be higher in the rural areas and within the poorer and least educated families. Poorly nourished, LBW, sick, and disabled children all are at particular risk of adverse outcomes and have special needs for care. Global progress in child health is attributable to a broad range of factors that include high coverage of good quality effective interventions, development programming, and strategic delivery of health services, along with improvements in education, child protection, respect for human rights, and economic gains in developing countries.

Key points

- ◆ Approximately two-thirds of under-5 deaths could be prevented by universal coverage of a small set of existing interventions that do not require expensive technology. Among these interventions, the promotion of breastfeeding, management and prevention of neonatal conditions, ARIs, diarrhoea, malaria, and HIV infection, in addition to improved feeding have the highest impact in reducing child mortality.
- ◆ Reduction in neonatal mortality requires increased effective coverage of interventions during pregnancy, childbirth, and in the postnatal period.
- ◆ Coverage with the key earlier-mentioned interventions remains low. Integrating the interventions into packages of care that are organized along a continuum from pregnancy, birth, neonatal period, and childhood, and delivered at all levels—from the home and community through the first-level facility and hospital—would contribute to improved efficiency in intervention delivery and to the achievement of high coverage.
- ◆ Strengthening the health system will be key for increasing the coverage and quality of health interventions.
- ◆ The development of an operational plan to which programmes can be held accountable, along with a good financing and human resource strategy, will yield long-term benefits for the child and the health system at large and is an essential element to follow the development of a child survival strategy.

Adolescent health

Pierre-André Michaud, Anne-Emmanuelle Ambresin, Richard F. Catalano, Judith Diers, and George C. Patton

Adolescence and youth: definition, biopsychosocial development, and demography

The terms ‘youth’, ‘adolescents’, and ‘young people’ are used to describe people in the transition from childhood to adulthood. The World Health Organization (WHO) defines ‘adolescents’ as people aged 10–19, ‘youth’ as those aged 15–24, and ‘young people’ as those aged 10–24 (WHO 1989; Sawyer et al. 2012). Defining this life phase by age has some value in both measurement of health and programming but in reality adolescence is better viewed as a life phase that varies in timing between individuals and cultures. In this chapter, we will interchangeably use the words ‘adolescents’ and ‘young people’, as the categories are arbitrary and the health problems faced are similar.

In most cultures and individuals, adolescence begins with the appearance of overt physical signs of puberty and ends with the acquisition of the statute of adulthood and/or parenthood, the whole process leading to greater emotional and social autonomy (Patton and Viner 2007). Adolescence is largely shaped by biological and socioeconomic factors. At an individual level, there is a 4–5-year variation in the onset of puberty (‘pubertal timing’) even where living conditions are similar for all members of a group. The age at which the physical changes linked with puberty occur does, to some extent, shape the psychosocial development of the individual and the adoption of health risk behaviours (Michaud et al. 2006): young people whose puberty begins earlier tend to engage in exploratory or risky behaviours at an earlier age than those who mature later. In Western countries, pubertal timing has decreased by 4–5 years over the past 150 years so that the mean age for menarche, a late pubertal event in females, is now 12–13 years in most high-income countries (Ong et al. 2006; Patton and Viner 2007) whereas it was around 16–17 years two centuries ago. The secular trends in the timing of puberty are in part related to improved nutrition.

Brain development is active throughout adolescence and actually continues to the end of the third decade of life (Giedd 2008; Sawyer et al. 2012). Puberty and its hormonal surge triggers the development of subcortical structures involved in the arousal of emotions and sensations (Dahl 2004). In contrast, the development of the prefrontal cortex, which is implicated in planning complex cognitive behaviour, personality expression, decision making, and

moderation of social behaviour, is not complete until young adulthood. This gap in the pace of the maturation of different parts of the brain may account for adolescence being a period of heightened impulsivity and emotional responses as well as of vulnerability to problems related to emotional control (United Nations Children’s Fund (UNICEF) 2011).

In pre-industrial societies, the adolescent transition from puberty to adult roles, as defined by the onset of sexual activity, marriage, and parenthood, ranged from around 2 years in girls to 4 years in boys. In today’s developed economies, longer periods of education and the availability of effective contraception means that adolescence commonly persists for well over a decade. The lengthening of adolescence has thus been accompanied by a later acquisition of professional capabilities and independence that are the hallmarks of an adult status (Patton and Viner 2007; UNICEF 2012) yet allowing a more sophisticated level of professional skills. Finally, with the emergence of new electronic media, young people around the world have access to information that was not previously available (UNICEF 2012). The spreading of the Internet and information and communication technologies represents an opportunity for adolescents in low- and middle-income countries (LMICs) to gain unprecedented skills and capabilities. It has also created a new means of socialization in which young people can engage with others across the globe.

There are considerable variations between individuals in both biological and psychosocial aspects of development. Yet a division of adolescence into three phases has retained its heuristic value:

- ◆ Early adolescence is characterized by puberty and rapid physical growth, with a marked interest in one’s self-image.
- ◆ Middle adolescence represents a period of experimentation potentially associated with risky behaviours such as unprotected sexual intercourse, and the use of legal and illegal psychoactive substances. Many risk behaviours are transitory and it should be kept in mind that exploration intrinsically belongs to child and adolescent development (Dahl 2004). However, some can lead to long-term morbidity, such as tobacco use or unsafe sex resulting in an HIV infection.
- ◆ Late adolescence is a period of progressive stabilization during which young people tend to form more stable relationships and acquire long-term perspectives, a developmental process which extends into early adulthood.

Health of adolescents in the global public health context

Today's generation of young people is, relative to other age groups, the largest in history. With a population of 1.8 billion, 10–24-year-olds now comprise over a quarter of the global population. This large increase in the youth population arises from improved infant and child survival following dramatic improvements over the past 50 years in maternal antenatal care, acute childhood illness, and malnutrition. Nearly 90 per cent live in LMICs where they may comprise more than a third of the population.

Adolescents have been a major focus in recent global approaches to sexual and reproductive health. A life-course perspective also places adolescents centrally in other health agendas including the prevention of non-communicable diseases, mental disorders, and injuries (Innocenti Research Centre 2007; Temin and Levine 2009). A cluster of health risk behaviours and states that largely start in adolescence (tobacco, alcohol, obesity, physical inactivity) are potential drivers of future non-communicable diseases in adults (Beaglehole et al. 2011). This adolescent contribution to disease burden in those over 60 years old includes high blood pressure, cholesterol, and glucose (29 per cent); tobacco use (10 per cent); physical inactivity (7 per cent); and overweight and obesity (7 per cent) (Gore et al. 2011). A range of global factors has come into play in shaping the health of young people. Perhaps the most immediate effect is the widespread dissemination of values and lifestyles that are potentially damaging to health. Tobacco use, alcohol and other substance use, physical inactivity, and obesity have spread rapidly to many LMICs in the last two decades. Indeed rates of adolescent tobacco use have diminished in many high-income countries whereas elsewhere rates are escalating rapidly.

In comparison to younger children, adolescents have seen fewer health gains. In a study of 50 countries with longitudinal data, the mortality of children had declined by over 80 per cent in the last 50 years. In contrast, mortality among adolescents had improved only marginally and there has been a reversal of historical mortality patterns in which early childhood mortality exceeds adolescent deaths. Over that time causes of death in adolescents have changed with a fall in infectious deaths in most high- and middle-income countries and a rise in deaths due to injuries, that now account for around 40 per cent of all adolescent deaths globally. Causes of injury death include suicide, motor vehicle injury, and homicide, with a major difference in patterns and rates of death in different parts of the world. In contrast, in low-income countries in sub-Saharan Africa and southern Asia infectious diseases, including HIV, tuberculosis, malaria, and maternal causes remain major contributors to death in young people. Moreover, as recently stated by Capua et al. (2013), 'Coverage rates for the adolescent vaccinations continue to lag behind those of the childhood vaccinations, despite their importance', even in high-income countries. Adolescents need both boosters and new vaccines such as the one against human papilloma virus (HPV) (see 'Sexual and reproductive health' section).

Young people bear a substantial disease burden in all regions of the world, both in terms of years of life lost (YLL) and years of life lost due to disability (YLD). Overall they account for over 15 per cent of the total disability-adjusted life year (DALY) toll

for all age groups and are the only age group where disease burden is higher in women than men. Africa has the highest regional rate of disease burden for those aged 10–24, 2.5 times greater than in high-income countries that have the lowest. The major global causes of disease for those aged 10–24 are neuropsychiatric conditions for both sexes, injuries in males, and maternal conditions in females.

We now also recognize ways in which the health of adolescent girls affects the health of the next generation. The influences range from viral infections such as rubella and HIV, maternal malnutrition and micronutrient deficiency, obesity and gestational diabetes, and health risks associated with alcohol, tobacco, and illicit and psychotropic drugs use (Bhutta et al. 2011).

Health-specific issues

Injuries and inflicted violence against and among adolescents

Injuries among young people include sports and traffic accidents, interpersonal violence, war, and suicide (see 'Mental health' section). Injuries account for substantial mortality and morbidity during adolescence (WHO 2002b, 2008; Patton et al. 2009; Gore et al. 2011). Apart from sub-Saharan Africa, where HIV leads to a large proportion of deaths, in the rest of the world, injuries among adolescents make up almost half of deaths in males. Worldwide, the death rates among males aged 10–24 years are around 14 per cent from road traffic injuries, 9 per cent from interpersonal violence, 6 per cent from self-inflicted injuries, 5 per cent from drowning, and 3 per cent linked with war; among females, the respective rates are 6 per cent from self-inflicted injuries, 5 per cent for road traffic injuries, and 2.5 per cent from drowning. Consequently, for males aged 10–24 years, traffic accidents, violence, and self-inflicted injuries account for 14 per cent of DALYs (197/100,000), while among females, they represent 5.6 per cent (66/100,000) (Gore et al. 2011).

The road traffic accident rate has increased alarmingly in some LMICs and now accounts for 90 per cent of the world's road traffic fatalities. Among explanations is the growth of motorized transport, the lack of education in driving skills, and, perhaps more importantly, poor roads and other infrastructure, lack of car safety, lack of legislation around seat belts, and the use of alcohol. WHO predicts that the road traffic injuries rate will rise to become the fifth leading cause of death by 2030 (WHO 2009). Most traffic injuries occur among 'vulnerable' individuals, that is, pedestrians, cyclists, or users of two-wheelers. Four main types of strategies can be developed to address traffic injuries (Munro et al. 1995): modifying the road environment, increasing the safety of vehicles, providing guidance and support, and reducing the exposure of young people to traffic.

Many adolescents are involved in physical fights: during early adolescence these are often linked with various types of conflicts, while during later adolescence they are linked with involvement in the drug trade and other forms of illegal activities. Unemployment is probably the single most important risk factor for such behaviour. The percentages of interpersonal violence vary from one country to another; for example, in Malawi, 24 per cent of males and 21 per cent of females report such events, while the percentages are 68 per cent and 74 per cent respectively in Djibouti. Among males, interpersonal violence is the second most

common cause of violent deaths: in South America, it is the most frequent cause of death as well as the leading cause of DALYs, both among males and females: in Salvador for instance, the death rate for males due to homicide is 157/100,000, a rate that is higher than the one due to road traffic accidents (UNICEF 2012). In the United States, the rate of death from homicide is as high as 18/100,000 (3/100,000 among girls).

Among factors playing a role in the occurrence of violence is the economic and political situation of the country. For example, countries which have the largest gap between richer and poorer inhabitants (as measured by the Gini index¹) have higher rates of violence among adolescents overall (Viner et al. 2012). Violence prevention needs to address risk factors at the individual, family, community, and societal levels (Dahlberg and Potter 2001) as outlined in the section 'Prevention and health promotion'.

Mental health

Mental disorders are estimated to be the leading cause of disease burden for young people across the globe. In countries where mortality from infectious disease and maternal causes is low, mental disorders and substance abuse account for over half the disease burden arising in adolescents. Globally, major depression accounts for the highest proportion (8.2 per cent) of disease burden in 10–24-year-olds. Schizophrenia (4.1 per cent), bipolar disorder (3.8 per cent), alcohol use disorders (3.0 per cent), and self-inflicted injuries (2.8 per cent) are also in the ten leading causes of disease burden in young people.

A question of whether there have been secular trends towards higher adolescent rates and earlier onset of common mental disorders and substance abuse has attracted a good deal of attention. There are some conflicting reports, in part related to limited available survey data before 1980, with some of the rise likely to have occurred prior to this (Rutter and Smith 1995; Costello et al. 2006). In industrialized countries, the clearest increases have been documented in the areas of substance use, eating disorders, and conduct disorders ('antisocial behaviour') (Hagell 2012). There have been sharp recent rises in the visits to doctors by adolescents for depression reported in high-income countries (Ma et al. 2005), higher rates of depression and anxiety disorder in later cohorts in retrospective studies of adults (Kessler et al. 2005), and data from recent surveys in the United Kingdom and Europe to suggest that rates of adolescent emotional problems have increased (Collishaw et al. 2004). Changes in the social context of development and lifestyles adopted by adolescents are commonly cited as reasons for the shift but there remains a lack a clarity about which specific changes may be responsible.

There are challenges in providing clinical care for adolescent mental disorders. Adolescents are often reluctant to seek help or communicate around mental health problems in a way which is readily identifiable by family, teachers, or other adults (Tylee et al. 2007). For this reason the adoption of youth-friendly practice (also see 'Youth suicide and self-harm' section) is particularly relevant in the management of mental disorders (Sanci et al. 2010). Secondly, it may be difficult to distinguish more transient emotional problems from disorders that become debilitating and persistent. It seems clear that many adolescents can fulfil criteria for a DSM-IV mental disorder but that many do not persist in this form into adulthood (Copeland et al. 2011). This may be particularly true of more serious mental disorders such as bipolar disorder and

schizophrenia where the early symptoms may be non-specific and not diagnostic. Most mental disorders in adolescents will be managed in primary care, where key competencies for health workers include being able to communicate well with young people, screen for mental health problems, and to provide treatments which include counselling, brief psychotherapy, and appropriate psychotropic medication.

Youth suicide and self-harm

Suicide and self-harm become prominent during the adolescent and young adult years in many countries and globally constitute the second leading cause of death in young people. Worldwide, it is estimated that there are at least 160,000 deaths from suicide in young people aged 15–24 years each year. In high- and middle-income countries with low rates of death due to infectious and maternal causes, it accounts for an even larger proportion of deaths. Typically rates are higher in males than females but with exceptions such as rural China and rural India where female rates are as high (Patton et al. 2009; Bergen et al. 2012).

By comparison with suicide, self-harm is relatively common. Around one in 20 young people in their mid-teens in high-income countries report some self-harm, typically self-laceration or self-poisoning, in the previous 12 months (Hawton and James 2005). Typically self-harm is a transient phenomenon with most self-harmers ceasing within a few months (Moran et al. 2012). Even so, self-harm is an important risk factor for premature death, with a minority of these deaths due to suicide. Self-harmers have high rates of death due to accidental injury and in later life from non-communicable diseases including cancer and cardiovascular disease (Bergen et al. 2012). In part this is likely to be mediated through high rates of health risk behaviours that include substance use and abuse.

Both suicide and self-harm in young people are commonly accompanied by mental disorders that include depression, substance abuse, and personality characteristics that include impulsivity and poor social problem-solving skills (Bergen et al. 2012). In addition, dysfunctional social networks such as being disconnected from community and family ties, parental separation, experience of bullying, and a history of sexual or physical abuse are common in the background of young suicide victims and self-harmers.

Approaches to prevention of suicide have commonly relied on population-based strategies that limit access to lethal means such as guns, lethal poisons, agricultural chemicals, pharmaceutical products that have high fatality rates (paracetamol), or preventing jumping from popular suicide destinations. Screening programmes to identify high-risk youth have had some attention and can increase mental health service use but do place a substantial burden on schools and have high false negative rates (Gould et al. 2009). Treatment studies have been few, but smaller-scale studies raise the possibility of brief psychological therapies being effective in adolescent self-harm (Donaldson et al. 2005).

Substance use and misuse

Substance use disorders including those related to alcohol use become prominent in the later adolescent and young adult years and represent the leading risk factor for disease burden in this population. Alcohol misuse in this age group accounts for a similar burden of disease as HIV. However, substance misuse is also a

major contributor to mortality and disease-related disability later in life. Tobacco use commonly begins during the adolescent years but is a major contributor to disease burden later in life.

The global epidemiology of substance use in adolescence is changing rapidly with increases in use being clear in many LMICs. A recent report on the health of the world's adolescents found comparable data on tobacco use across six countries, representing 45 per cent of the worldwide population of young people (Patton et al. 2012). Rates of early tobacco use were high in Austria, Chile, Malta, and Namibia in both boys and girls. European regions, Latin America, North America, and many sub-Saharan African countries also show rates of tobacco use similar for boys and girls. Indonesia, Jamaica, Jordan, most Asian regions, the Caribbean, and the eastern Mediterranean have higher rates of tobacco use among boys.

Data on binge drinking were available for 50 countries and 18 per cent of the worldwide population. Estimates for binge drinking from high-income countries were somewhat higher than those derived from LMICs, with the exception of some Latin American countries. Austria, Ireland, and the United States had the highest rates with close to a third of children aged 15 years reporting binge drinking in the past month. Data on cannabis misuse in the past 30 days were available in 40 countries representing 12 per cent of the worldwide population, with the best data available for the European regions and North America. There were substantial variations in rates of use, with the highest in Canada, France, the Netherlands, Spain, and the United States. Intravenous drug users constitute a very vulnerable population, with a high degree of malnutrition, chronic skin infections, unplanned pregnancy, and a high rate of sexually transmitted infections (STIs), including hepatitis B and C and HIV. Adolescents who start using drugs at an earlier age are at higher risk of becoming injecting drug users (Trenz et al. 2012); this is also true for young people who drop out of education or experience homelessness, this holds true for both the United States as well as countries undergoing huge societal change such as Russia (Niccolai et al. 2011).

There is a range of reasons to take adolescent substance misuse seriously. Heavy adolescent use (e.g. misuse) may have profound adverse physical (e.g. blood-borne transmissible disease including HIV and hepatitis C) and psychological effects (e.g. psychotic and anxiety disorders related to cannabis use), as well as impairing social development (e.g. school failure and unemployment). Secondly, heavy use of alcohol and other psychoactive substances increases the likelihood of unprotected sex, unwanted pregnancies, dangerous driving, and interpersonal violence. Finally, the early initiation of substance use increases the likelihood of heavy and dependent use extending into adulthood, with many negative health and social consequences for users and their families (Patton et al. 2007).

Sexual and reproductive health

There is no area that has been more influenced by the biological and societal shifts reviewed at the beginning of this chapter, as has the sexual and reproductive health of young people. Both societal transformation (including cultural and social norms) and behavioural patterns create a situation of unique vulnerabilities as well as unique opportunities to build on young people's sexual and reproductive health assets such as the knowledge and skills to avoid unplanned and/or early pregnancy, STIs

including HIV, and sexual violence and abuse. An important issue during adolescence is the acquisition of a stable sexual orientation. LGBT (lesbian/gay/bisexual/transsexual) youth often endure difficulties in their coming out process, especially in certain cultural contexts that condemn homosexuality. It has been repeatedly shown that LGBT adolescents have a higher rate of mental difficulties and of suicidal conduct (Society for Adolescent Health and Medicine 2013). Another issue is the one of 'intergenerational cycle', a concept which stresses the fact that some behaviour patterns such as unintended pregnancy and fatherhood among adolescents tend to persist from one generation to another: multidimensional approaches including education represent an effective way to overcome this phenomenon (de Almeida Mda and Aquino 2009).

In almost all countries regardless of development status, the gap between the first sexual intercourse and marriage is widening, which means that most early sexual experiences occur among unmarried young women and men. However, an estimated 100 million adolescent girls in this decade will have their first sexual intercourse while married (nearly one in every four girls) and most likely with an older partner, with the consequence that they do not have the power to influence contraceptive or condom use (Wellings et al. 2006). The age at which adolescents tend to engage in sexual experiences varies, depending on contextual and cultural factors. In Latin America, 17 per cent of adolescent girls aged 15–19 years have had sex before age 15, in sub-Saharan Africa this figure is 14 per cent, and in South Asia the proportion is 8 per cent (UNICEF 2012).

The use of effective contraception among 15–24-year-olds has increased considerably since the early 1990s (Lloyd 2005). According to the most recent data available, contraceptive use was around 12 per cent in Africa, between 42 and 68 per cent in Latin America, between 13 and 47 per cent in Asia, and between 21 and 38 per cent in the Middle East among married and unmarried adolescents aged 15–19 years (Blanc et al. 2009). By contrast, 82 per cent of sexually active 15-year-olds in Europe and Canada reported having used condoms or contraceptive pills at last intercourse (Godeau et al. 2008). In countries with high rates of HIV, the proportion of adolescents using male condoms has also improved. For example, the rates of boys aged 15–19 years using male condoms vary between 40 (e.g. in United Republic of Tanzania, Uganda, and Malawi) and above 70 per cent (e.g. in South Africa, Namibia, and Swaziland) (UNICEF 2012). Early pregnancy represents a risk factor for poor reproductive outcomes. A recent review from the WHO stresses various preventive strategies such as increasing education and sexual education, the introduction of social support programmes, or prevention of unsafe abortion (Chandra-Mouli et al. 2013).

STIs, including HIV and HPV, constitute another important threat to health, as adolescents (especially young inexperienced individuals) are particularly vulnerable to acquiring such infections. Prevention strategies include individual screening, sexual education, and large-scale information campaigns (Berlan and Holland-Hall 2010). Among all potential approaches to improve safe sexual behaviour, retention in school seems to be effective. For instance, Baird and colleagues have recently shown a decrease in HIV infection rates among women receiving cash to stay in school (Baird et al. 2012). Finally, the introduction of HPV vaccine, even if it has been slow in low-income countries, is another

effective preventive strategy in the area of STIs (Markowitz et al. 2012).

Chronic conditions, including malnutrition and obesity

As the importance of infections is decreasing around the world, thanks to vaccination, pharmacological treatments, and the improvement of hygiene, non-communicable diseases more and more constitute a real challenge. As stated by Proimos et al. obesity, childhood cancer, congenital defects and use of tobacco, alcohol, and drugs are and will be on the increase in the coming years. Indeed, around 10 per cent of adolescents suffer from some type of chronic condition broadly defined as conditions necessitating some care for at least 6 months (Suris et al. 2004), most of them belonging to the so-called 'non communicable diseases'. Chronic conditions encompass wide-ranging conditions, going from a mere myopia to cancer, cystic fibrosis, or myopathies and dystrophies. Among chronic conditions, mental disorder is a leading cause of DALYs among adolescents and includes unipolar depressive disorders, alcohol use disorders, self-inflicted injuries, schizophrenia, and bipolar affective disorders (see 'Mental health' section) (Patel et al. 2007). Given the improvement in medical care of many severe conditions, many individuals currently survive into adolescence and adulthood, where formerly they would not have survived past infancy. The increase in survival rate is thus directly associated with an increase in prevalence of chronic conditions.

Most chronic conditions affect the adolescent's biopsychosocial development and well-being. The extent of this impact depends on age of onset, duration, whether they are visible or not, congenital or acquired, expected survival, mobility, physiological functioning, cognition, emotional/social impairment, sensory functioning, communication impairment, course, and uncertainty (Suris et al. 2004). Areas affected may include growth and puberty, self-esteem, isolation from peers or overprotection by parents, and lack of school or professional achievement. Thus these issues will have to be dealt with more and more by the healthcare system. Its challenge will be to develop adequate and efficient ambulatory or inpatient care, thus improving the efficacy of treatments and therapeutic adherence of these youngsters in the short and long term (WHO 2002a; Narring et al. 2004).

Chronic malnutrition in earlier years is responsible for widespread stunting and adverse health and social consequences throughout the lifespan, including underweight. For instance, in Bangladesh, Senegal, and Niger, a third of female adolescents are underweight (UNICEF 2012). This is best prevented in childhood but actions to improve access to food could benefit adolescents as well. Anaemia is one of the key nutritional problems in adolescent girls, and in many African countries, more than half of female adolescents are anaemic (UNICEF 2012). Preventing teenage pregnancy and improving the nutritional status of girls before they enter pregnancy could reduce maternal and infant morbidity and mortality, and contribute to breaking the cycle of intergenerational malnutrition.

Over the past decade WHO has recognized that overweight and obesity represent a major public health challenge, reaching pandemic proportions among adults as well as among children and adolescents (Wang et al. 2002; UNICEF 2012). This pandemic was first observed and is still prominent in the United States and

Western Europe, but has also occurred in middle-income countries such as Eastern Europe, South America, and East Asia. For instance, in Maldives, Bolivia, and Brazil, around a quarter of adolescent girls are overweight (UNICEF 2012). The prevalence of overweight and obesity has increased markedly in the last two decades in most high- and middle-income countries (Wang et al. 2002). This trend has arisen as a result of obesogenic environments, more sedentary time with diminished physical activity, and increasing calorie consumption. Urbanization encourages the use of automobiles and other motorized vehicles; in many high-income countries, suburbs lack shops, entertainment, or other destinations within walking distance.

Service delivery and early clinical interventions

There are sound reasons for offering effective healthcare and early individualized preventive service for adolescents. These years coincide with major shifts in disease burden and the adoption of lifestyle and health risk behaviours that have substantial effects on later health (see 'Health-specific issues' section). Moreover, healthcare through service delivery is one of the fundamental rights relevant to youth among others like gender equality and the right to education (United Nations 2003).

There is growing recognition that health service delivery should be tailored to the particular developmental needs of youth as well as the preventive orientation necessary for this age group. In 2002, the WHO called for the development of adolescent-friendly health services (AFHS) worldwide (WHO 2002a). The five themes underpinning AFHS are equity, effectiveness, accessibility, acceptability, and appropriateness of care. Although initially focused on primary healthcare in low-income countries, this framework has the potential to promote best practice healthcare for adolescents in high-income countries and within specialist health services as well (Tylee et al. 2007; Viner 2007).

Accessibility and acceptability of services remain key barriers to effective service delivery (Tylee et al. 2007). The reasons adolescents don't use services when they are available are: cost, lack of convenience (e.g. health facilities might be located a long distance from where young people live or have inconvenient opening hours), or lack of publicity and visibility. In some parts of the world, services are not provided due to geographic, financial, or attitudinal restrictions. Fear of a lack of confidentiality is a further major reason for young people's reluctance to seek help. When young people do seek help, they are often unhappy with the style of consultation and then don't return for follow-up (Tylee et al. 2007).

Professional organizations such as the American Medical Association have provided guidelines for adolescent preventive services (Elster and Kuznets 1994) that allow for the early detection of health problems that would potentially benefit from early intervention. Among these recommendations is the importance of screening young people for psychosocial issues and health risk behaviours. 'HEEADSSS' is a simple mnemonic screening tool, designed to cover the main risk areas among young people (see Table 10.4.1) (Goldenring and Rosen 2004).

These screening guidelines are based on the assumption that once a problematic behaviour is identified, the delivery of an intervention will contribute to modify the natural course of such

Table 10.4.1 HEEADSSS

HEEADSSS mnemonic	Examples of questions to assess the HEEADSSS
Home	Who lives with you? Where do you live? Do you have your own room? What are relationships like at home?
Education/employment	How are your grades? Any recent changes? Any dramatic changes in the past? What are your future education/employment plans/goals?
Eating	Have you dieted in the last year? How? How often? Have you done anything else to try to manage your weight? How much exercise do you get in an average day? Week?
Activities	What do you and your <i>friends</i> do for fun? (with whom, where, and when?) What do you and your <i>family</i> do for fun? (with whom, where, and when?)
Drugs	Do any of your friends use tobacco? Alcohol? Other drugs? Does anyone in your family use tobacco? Alcohol? Other drugs? Do you use tobacco? Alcohol? Other drugs? Is there any history of alcohol or drug problems in your family? Does anyone at home use tobacco?
Sexual activity	Have you ever been in a romantic relationship? Tell me about the people that you've dated. OR Tell me about your sex life. Have any of your relationships ever been sexual relationships? Are your sexual activities enjoyable? What does the term 'safer sex' mean to you?
Suicide and depression	Do you feel sad or down more than usual? Do you find yourself crying more than usual? Are you 'bored' all the time? Are you having trouble getting to sleep? Have you thought a lot about hurting yourself or someone else?
Safety	Have you ever been seriously injured? (How?) How about anyone else you know? Do you always wear a seat belt in the car? Have you ever ridden with a driver who was drunk or high? When? How often? Is there any violence in your home? Does the violence ever get physical? Have you ever been physically or sexually abused? Have you ever been raped, on a date or at any other time? (If not asked previously)

behaviour, be it substance misuse, an eating disorder, or unsafe sex. In other words, early intervention refers to interventions targeting adolescents displaying the early signs and symptoms of a health problem or experiencing a first episode of illness such as a mental disorder, for example. Ideally, these interventions should occur shortly after a need has arisen, aiming to reduce distress, shorten the episode of care, enhance protective factors, and minimize the level of intervention required.

As discussed previously, the shifting patterns of disease among adolescents have driven interventions to be more focused on non-communicable and non-fatal causes of disease both in adolescence and into adult life in order to respond to this shift and have a greater impact on public health outcomes. Current early intervention efforts have focused on ten main areas: physical activity, nutrition, tobacco, alcohol and other drugs, family planning, mental health, violent and abusive behaviours, unintentional injuries, sexually transmitted diseases, and clinical preventive services. For example, clinical intervention in an emergency room to reduce unintentional injuries showed that adolescents receiving counselling in a single risk area increased the use of seat belts and

bicycle helmets compared to the controls (Ketvertis et al. 2003). Other examples showing effectiveness of early intervention are programmes of tobacco cessation combining a variety of approaches, including taking into account the young person's preparation for quitting, supporting behavioural changing and enhancing motivation (Grimshaw and Stanton 2006). Early brief interventions using motivational interviewing and counselling help in the reduction of consumption of drugs and alcohol (Jensen et al. 2011).

Prevention and health promotion

Adolescent-onset behavioural problems implicated in non-communicable diseases include unsafe driving, mental health, violence, alcohol, tobacco and drug misuse, as well as unsafe sex and teen pregnancy (Patton et al. 2009). These health risks are all largely preventable. Over the last 40 years the integration of life course research with prevention trials and community epidemiology has offered a new way forwards in adolescent health (O'Connell et al. 2009). This prevention science framework posits that to prevent the onset of a problem, one must change the factors

Table 10.4.2 Risk factors affect multiple behaviour problems

Risk factors	Substance use	Delinquency	Teen pregnancy	School dropout	Violence	Depression and anxiety
Community

Rebelliousness	✓	✓		✓	✓	
Friends who engage in the problem behaviour	✓	✓	✓	✓	✓	
Favourable attitudes toward the problem behaviour	✓	✓	✓	✓	✓	
Early initiation of the problem behaviour	✓	✓	✓	✓	✓	
Constitutional factors	✓	✓			✓	✓

A tick at the intersection of a row and a column on this table indicates that there are at least two longitudinal studies that demonstrate that the risk factor measured earlier in an adolescent's life predicts the behaviour problem during adolescence. that predict it (Coie et al. 1993; O'Connell et al. 2009). Such factors are commonly termed risk and protective factors and include those from an individual's family, school, and peer contexts as well as individual factors. Risk factors increase the likelihood of problems, and protective factors either directly decrease the likelihood of problems or mediate or moderate exposure to risk (O'Connell et al. 2009).

Table 10.4.2 lists risk factors for multiple problem behaviours. There is a good deal of commonality in risk factors across problem behaviours, suggesting that prevention programmes that seek to reduce, for example, family management problems or academic failure are likely to prevent multiple problems despite the fact that the programmes themselves may be focused on single problems such as conduct problems or academic success.

Although there has been less research on protective factors, longitudinal, prospective studies have identified seven factors that promote positive social development and reduce behaviour

problems, including individual factors: high intelligence; resilient temperament; social, emotional, and cognitive competence; and environmental factors: opportunities for prosocial involvement; recognition for positive involvement; bonding; and healthy beliefs and standards for behaviour (Catalano et al. 2011).

Prevention science has utilized this knowledge about risk and protective factors to design preventive interventions to reduce risk and enhance protection. A growing number and diverse array of preventive interventions have been tested in controlled trials and found to be efficacious in preventing adolescent health problems (O'Connell et al. 2009). In a recent review of prevention programmes, Catalano and colleagues (2012) examined the evidence from controlled trials across multiple behaviour problems including obesity, violence, mental health, substance use, traffic crashes, pregnancy, and STIs by examining recent reviews and conducting targeted searches for controlled preventive trials. While only presenting illustrative examples in their article,

Table 10.4.3 Types of approaches that have controlled trials demonstrating efficacy

Prevention programmes/policies	Violence	Drug use	HIV STI	Unintended pregnancy	Vehicle crashes	Obesity	Mental health

Table 10.4.3 provides the results of the more comprehensive programme review across multiple problems. A check at the intersection of a row and a column indicates that there is at least one controlled prevention trial of the approach with evidence of impact post intervention on an indicator of the behaviour problem in the column. While most of these studies were conducted in high-income countries, a number have been conducted in LMICs. The reader is referred to high-quality reviews of controlled prevention trials available from the Center for the Study and Prevention of Violence (n.d.), The Cochrane Collaboration (n.d.), and The Campbell Collaboration (n.d.) for reviews of specific programmes. Many behaviour problems have common risk and protective factors, and there is evidence that interventions that address these common risk factors have affected multiple problems despite the prevention programme focus on only a single behaviour problem (Flay et al. 2004; Schweinhart et al. 2005; Hawkins et al. 2008).

Table 10.4.3 suggests that wide-ranging prevention strategies are effective from pre- and postnatal home visiting programmes; early childhood education; primary and secondary school programmes to improve instruction, classroom management, and attendance; and school curricula that provide skills and norms that support avoiding problem behaviour, from risky sex, to drugs, to violence. A few illustrative examples follow.

The Gatehouse Project is a primary prevention programme which includes both institutional and individual-focused components to promote the emotional and behavioural well-being of young people in secondary schools. Using a school-based cluster randomized controlled trial, it has shown effectiveness on behaviours such as substance use by young people, with a 3–5 per cent risk difference between intervention and control students for any

drinking, any and regular smoking, and friends' alcohol and tobacco use across the three waves of follow-up (Bond et al. 2004).

Nurse–Family Partnership (NFP) is a programme in which trained, registered nurses provide low-income, single, first-time mothers with biweekly structured visits during pregnancy and for 2 years post birth. Nurses share information on how mothers can reduce their use of alcohol, tobacco, and other drugs during pregnancy; improve their prenatal health and diet; sensitively and responsibly care for their infants; achieve their own education and occupational goals; avoid unwanted future pregnancies; and access community services. The programme has been demonstrated in controlled trials to reduce the mother's reliance on public welfare (157 fewer days over 2 years), the number of subsequent births were reduced by 43 per cent, verified reports of child abuse and neglect (32 vs. 65 per cent) decreased, and mothers increased their workforce participation (82 per cent increase in months worked). Children at age 15 have been shown to have fewer arrests (20 vs. 45 per cent), and less alcohol use (1.09 vs. 2.49 days' drinking in past 6 months), and fewer lifetime sexual partners (0.92 vs. 2.48) compared to those not receiving services (Olds et al. 1998).

Strengthening Families Programme for Parents and Youth 10–14 is a 7-week universal parent training programme offered to parents and adolescents in weekly 2-hour sessions. The programme targets family, peer, and individual risk and protective factors, including parent communication and child management skills; children's social skills, stress management, and ability to refuse peer drug offers; and parent/child conflict resolution and bonding. Across multiple studies conducted in rural communities in the United States the programme has been shown to reduce substance use (24 per cent less alcohol use; 40.1 per cent less drunkenness) and delinquency (37–77 per cent less depending on the behaviour) up

to 5 years post intervention for participants versus control group members (Spath et al. 2001).

Conditional Cash Transfer (CCT) Programmes provide payments that come with conditions. Examples include payment of school fees and supplemental cash to poor parents with the condition that they send their child to school. Trials in Malawi and Kenya found reduced self-reported sexual activity (13 per cent less likely to ever have sex), pregnancy (31 per cent less likely), and marriage (41 per cent less likely) in one or both countries, and girls and young women who received the CCTs were 15 per cent less likely to drop out of school compared to controls (Duflo et al. 2006; Baird et al. 2010). Preliminary findings from the study in Malawi showed a 60 per cent reduction in HIV prevalence and a 75 per cent reduction in herpes simplex virus-2 prevalence (2010).

Unplugged is a 12-hour, teacher-led alcohol, tobacco, and other drug use prevention programme for early secondary school students. Lessons target peer influence and societal risks and aim to improve students' goal-setting, decision-making, and drug refusal skills. In a study of students in seven European countries, programme benefits included reduced any (odds ratio (OR) = 0.80) and frequent drunkenness (OR = 0.62) and frequent past-month marijuana use (OR = 0.74) (Faggiano et al. 2010).

Prevention approaches also include community policies and laws ranging from access to contraceptives for those under age 18 to graduated driving laws in which new drivers have restrictions on conditions under which they may drive, and raising the legal drinking age to 21 (Catalano et al. 2012). Two examples relate to health policy for mature minors and the use of taxation.

Policies that ensure minors' right to obtain contraception without parental notification or consent and provide contraception at no cost to minors have been associated with an 8.5 per cent decreased adolescent birth rate. Youth who were provided with contraception combined with sexuality education in school-based clinics were more likely to delay initiation of sexual intercourse (79 vs 90 per cent at age 17) and have lower pregnancy rates (pregnancy rate in intervention schools declined by 30.1 per cent versus an increase of 57.6 per cent in control schools) compared to youth not exposed to the intervention (Zabin et al. 1986).

Systematic reviews of multiple studies have shown that price and tax increases on alcoholic beverages have been associated with reduction in alcohol use by adolescents and young adults (aggregate-level $r = -0.17$ for beer, -0.30 for wine, -0.29 for spirits, and -0.44 for total alcohol), including excessive drinking and alcohol-related health problems (mean reported elasticity = -0.28 , individual-level $r = -0.01$, $p < 0.01$) (Wagenaar and Toomey 2002).

There is also growing evidence that these programmes can be cost effective. In the United States, Aos and colleagues estimated cost effectiveness of diverse prevention programmes (Aos et al. 2004). Their work demonstrated that, while not all prevention programmes realize monetary benefits, many do, returning between \$2 and 42 for every dollar invested (Catalano et al. 2012).

Community monitoring systems are an essential element of effective prevention programmes. These assess behaviour problems, as well as risk and protective factors, and can help communities apply prevention strategies relevant for that setting (Mrazek et al. 2004). Several local surveys exist that have been tested in multiple countries, including the Communities That Care (CTC) Youth Survey (Arthur et al. 2002) which measures risk, protection, and substance use, delinquency, violence, and depression, and the

European School Survey Project on Alcohol and Other Drugs (ESPAD) (Hibell et al. 2009) which focuses on assessing adolescent drug use and risks. The school-based Global Student Health Survey (GSHS) assesses nine problem behaviours and some predictors among young people aged 13–15 years (WHO 2004).

In the field of adolescent sexual and reproductive health and specifically of HIV prevention, a large review conducted by the WHO has drawn attention to the potential for effective interventions within the media or within schools settings (WHO et al. 2006). There are also a number of initiatives and programmes which have proven effective in preventing unplanned pregnancies among adolescents (Kirby 2007).

Also, several avenues have proven effective to address child and adolescent obesity, from primary to tertiary care. These include the involvement of the family, the schools, and the community in the care of overweight and obese adolescents, but also the development of strategies and policies which aim at improving the nutritional supply and environment of young people (Hassink et al. 2011). Indeed, adolescence is a timely period to shape healthy eating and exercise habits that can contribute to physical and psychological benefits during the adolescent period and to reducing the likelihood of nutrition-related chronic diseases in adulthood.

Finally, the prevention of injuries is mainly improved through environmental and legislative measures such as enforced control of firearms, mandatory use of helmets or seat belts, or improvement of roads (WHO 2008).

Despite the growing evidence that prevention can be effective, most preventive interventions have been developed in high-income countries (Catalano et al. 2012). Even in high-income countries like the United States, prevention approaches that are not effective or have not been evaluated are more widely used than prevention programmes that have been tested and found to be effective (Ringwalt et al. 2009). The underutilization of effective programmes in LMICs is even greater, where fewer prevention programmes have been tested (Catalano et al. 2012). One current challenge is how the use of tested, efficacious prevention policies and programmes can be extended globally while recognizing that communities and nations are different from one another, and need to decide locally what policies and programmes they use, because risk and protection factors as well as the cultural and the political context vary by community. Catalano and colleagues (Catalano et al. 2012) suggest three solutions to meet this challenge.

First, the marketplace (government, public health agencies, schools, and parents) must recognize that: (1) adolescent health is a priority, (2) behaviour problems are implicated in poor health outcomes in adolescence and adulthood, and (3) there are effective policies and programmes that can prevent behaviour problems. A shift of 10 per cent of the total funds spent on adolescent health and education to effective prevention policies and programmes could make a big difference in adolescent and adult morbidity and mortality worldwide.

Second, more research is needed on the impact of translating these efficacious approaches to a range of communities and across nations. Translation of effective approaches must recognize differences in local conditions, but also recognize that the policy or programme has active ingredients that need to be preserved in order for the programme to work. Some interventions created in high-income countries can be translated to and be effective in LMICs (Kirby 2007).

Third, using surveys to understand country and community epidemiology can help assess and address local needs with efficacious prevention programmes. By regularly assessing local risk and protective factors and behaviour problems in youth, communities and nations can understand and prioritize their need for specific prevention approaches.

Conclusion

The knowledge on global adolescent health has made rapid progress in recent years, demonstrating the substantial mortality and disease burden arising in this age group. It is a rapidly changing picture in which many countries are making a transition from high mortality and disability in infancy and younger childhood to one where the adolescent years are dominating the picture of mortality and disease burden in the developmental years.

There is now recognition that adolescence is central to major global health agendas beyond sexual and reproductive health. In injury, mental health, and risks for later life non-communicable diseases, it is difficult to conceive a successful strategy that does not address the onset of these problems in the adolescent years. In addition, there are major social and economic challenges that will continue to drive adolescent health and disease in the years to come. These include the ongoing economic difficulties in many countries, with resultant high youth unemployment, the rapid urbanization of many countries and loss of traditional communities, the growth in migration both within and between countries, and ongoing civil unrest and military conflict in many parts of the globe.

There are no simple answers to these considerable challenges. Rather, responses will need to be made at multiple levels and in the different settings in which young people are growing up. They include the provision of youth-friendly healthcare, the development, implementation, and evaluation of strategies at school and community levels for promoting the health development of the young, the implementation of legislative and environmental policies that take into account local culture and history, and the engagement of public health professionals with fields well beyond health in the implementation of these strategies.

Note

1. The Gini index/coefficient is a measure of the equality or inequality in incomes (or other indicators) which can be assessed across countries. Income Gini index is considered as an indicator of equity in a given country.

Ethnicity, race, epidemiology, and public health

Raj Bhopal

Introduction to ethnicity in relation to race and related variables

Humans comprise one biological species and their similarities, both genetically and behaviourally, are remarkable. Nonetheless, humans show differences between individuals and between groups (Bhopal 2014). Amongst the important concepts that help them differentiate themselves, ethnicity and race are particularly relevant to medical sciences, reflected in increasing numbers of publications (Afshari and Bhopal 2010). Remarkably, humans are mentally equipped to differentiate between individuals and groups, including by race-related physical features, from early infancy (Anzures et al. 2013; Xiao et al. 2013).

Race and ethnicity are complex, intertwining, and important concepts that are used by societies to identify and evaluate social groups and individuals. As epidemiology is based on variables that differentiate the health experiences of populations, race and ethnicity are central to the discipline, and to public health (Bhopal 2008). Table 10.5.1 sets out some criteria for a good epidemiological variable in relation to ethnicity, race, and their commonly used proxy of country of birth. Even though race has come under attack because of its historical harms (Kohn 1995), it remains important in public health, not least to help redress historical harms (Krieger 2003). Increasing international migration (see Chapter 10.9) has made these concepts of great contemporary importance (Segal et al. 2010) and the International Organization of Migration and the World Health Organization (WHO) are leading efforts to catalyse work in this field globally (WHO Regional Office for Europe 2010; WHO 2010).

Traditionally, race focused around subgrouping human populations based upon biological factors such as skin colour, facial shape, and hair type. Your race, based on this concept, is the group you belong to, or are perceived to belong to, in the light of such factors (Bhopal 2014). Racial classifications based solely on biology have proven of modest scientific value and questionable validity, and have been open to abuse socially, for example, the Nazi 'final solution' (Bhopal 2014). This concept of race is changing to incorporate social factors, and a shared history, and hence it is converging with ethnicity and in this renewed form remains important, especially in the United States (Satcher 2001). The new genetic technologies and genome analysis techniques are, however, leading to a reappraisal, and worryingly to a potential resurgence, of the biological race concept (Fujimura and Rajagopalan 2011).

Ethnicity is a concept that, in principle, uses cultural and social factors such as family origins, language, diet, and religion to subgroup humans. Your ethnicity, based on this concept, is the group you belong to, or are perceived to belong to, in the light of such factors (Bhopal 2014). Family origin is based in ancestry and in this respect ethnicity is akin to race. Ethnicity is in vogue, particularly in Europe, partly due to the abuse of the race concept politically (Bhopal 2007). In practice, race and ethnicity are often used synonymously, with the compound word race/ethnicity (or race-ethnicity) appearing, especially in the United States (Afshari and Bhopal 2010).

Race and ethnicity are related to but separate from nationality (the nation you belong to, as identified by citizenship and/or passport) and country of birth (Bhopal 2007). It is not only race but also other related characteristics such as ethnicity, religion, and migration status that are relevant to racism. Racism is the product of the view, and its expression through individual, institutional and social attitudes, conventions, and behaviours that some groups are superior to others on the basis of their race or related characteristics as above. Racism is then used to provide advantage to these ostensibly, but not in reality, superior groups.

Race and ethnicity are especially important to identity where people of different racial and ethnic groups mix, that is, multi-ethnic, multiracial, multicultural societies, themselves resulting from rapid immigration (Bhopal 2014; Segal et al. 2010; also see Chapter 10.9). Scientific disciplines have utilized race and ethnicity to advance both understanding and applications of research. The sheer complexity of the concepts has made this task difficult, and the misapplication of race and ethnicity has often done more harm than good (Kohn 1995; Bhopal 2007). Nonetheless, migration status, race, and ethnicity are excellent in differentiating the health and healthcare status of subpopulations, and this property gives them central status in quantitative health sciences, public health and clinical care (Table 10.5.1). Building on evolutionary thinking extended to modern times, I have created a model (Fig. 10.5.1). The left half of the figure shows how migration from and indeed within Africa some 60,000–70,000 years ago over several millennia led to differentiation among human populations. The genetic differences arising have been closely aligned in modern times with the concept of race, and cultural ones to ethnicity, but as we have seen these are merely issues of emphasis. There would have been differentiation in many other ways but I have limited these to socioeconomic and technological. The time period of 60,000–70,000 years was enough to cause

Table 10.5.1 Ethnicity (or race or country of birth) as an epidemiological variable

Criteria for a good epidemiological variable	Criteria in relation to ethnicity (or race or country of birth)
Impacts on health in individuals and populations	Ethnicity is a powerful associated influence on health
Accurately measurable	In most populations ethnicity is difficult to assess (not true for country of birth)
Differentiates populations in their experience of disease or health	Huge differences by ethnicity are seen for many diseases, health problems and for factors which cause health problems
Differentiates populations in some underlying characteristic relevant to health, e.g. income, childhood circumstance, hormonal status, genetic inheritance, or behaviour relevant to health	Differences in disease patterns in different ethnic groups reflect a rich mix of environmental factors and may also reflect population changes in genetic factors, particularly in populations where migration has been high
Generates testable aetiological hypotheses, and/or helps in developing health policy, and/or helps plan and deliver healthcare and/or helps prevent and control disease	It is hard to test specific hypotheses because there are so many underlying differences between populations of different ethnicity Ethnic differences in disease patterns profoundly affect health policy Knowing the ethnic structure of a population is critical to good decision-making By understanding the ethnic distribution of diseases and risk, preventative and control programmes can be targeted at appropriate ethnic groups

Reproduced from Raj. S Bhopal, *Ethnicity, Race, and Health in Multicultural Societies*, Second Edition, Table 1.3, p. 8, Oxford University Press, Oxford, UK, Copyright © 2014 Raj. S Bhopal, by permission of Oxford University Press.

differentiation but not enough to create new human species. In modern times, especially in the last 1000 years or so, new migrations have created multicultural societies. In these new societies immigrants come with the health status variations from their place of origin (whether effectively permanent as in genetic ones or highly changeable, e.g. low blood pressure). The effects of the migration process (e.g. selection effects), the journey, the new life circumstances, and discrimination at the new settlement

influence the health status. The complexity of the process is self-evident.

Race and ethnicity are important in health and healthcare, particularly in demonstrating inequalities (differences) and inequities (differences where there is a presumed or demonstrated element of injustice, called disparities in the United States) (WHO 2010). The analysis of such inequalities can lead to insights into the forces causing them and hence point to the actions required

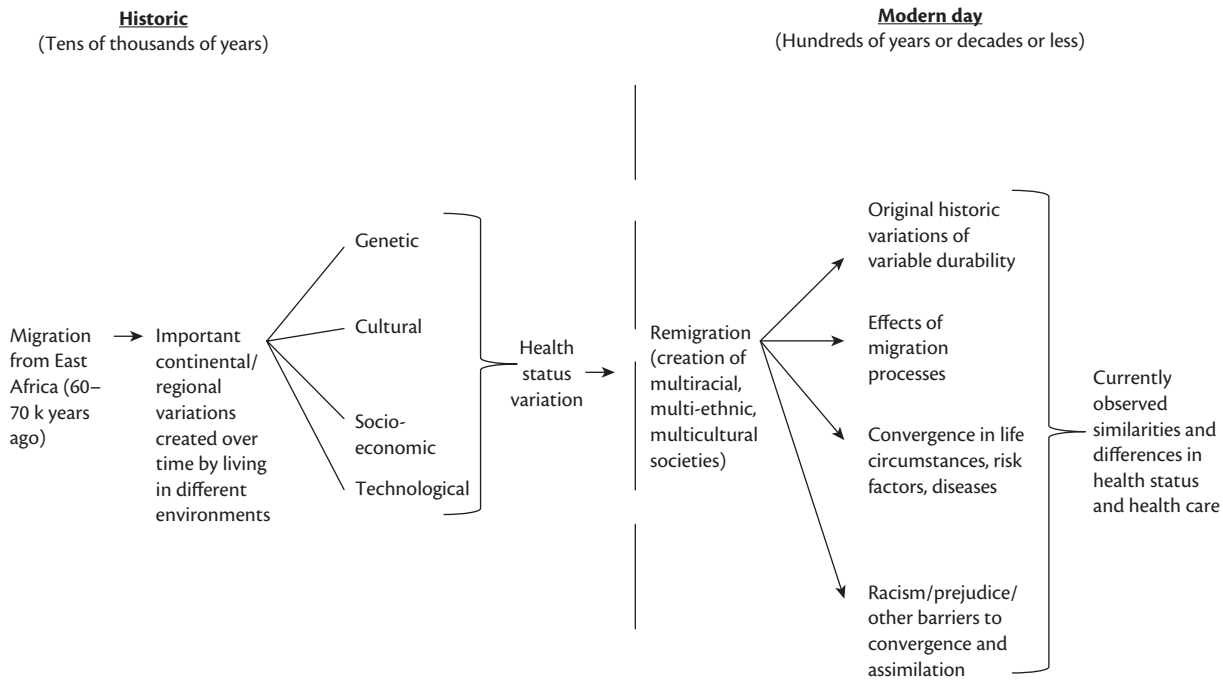

Fig. 10.5.1 Model linking evolutionary and current-day forces to produce variations in health status and healthcare by migration status, race, and ethnicity. Reproduced from Raj. S Bhopal, *Ethnicity, Race, and Health in Multicultural Societies*, Second Edition, Figure 10.1, p. 339, Oxford University Press, Oxford, UK, Copyright © 2014 Raj. Table 10.5.2 Potential problems and benefits of ethnicity and race in health sciences

Issue	Potential problems	Potential benefits
Credibility	Gives backing to scientifically difficult concepts that have been abused previously	Utilizing concepts in health sciences will lead to their development and improvement and to health improvement
Division of society	Reducing social cohesion, by an emphasis on differences, and the creation of a sense of inferiority and superiority	Helping heal existing social divisions by acknowledging and working on differences, as well as demonstrating similarities
Racism	Provides information that can be abused by those who wish to demonstrate inferiority and superiority of particular groups	Information can combat past injustices, and guide future actions to prevent such racism
Ethnocentricity	Sets a standard usually based on the majority population that may be inappropriate for a particular ethnic group	By demonstrating that in some respects ethnic minority populations have better health, more challenging standards can be set for the population, including the majority, e.g. the standard is the population with the best health
Emphasis on problems	Stigmatizing and stereotyping minority populations by focusing on conditions where their health is worst	By showing that in some respects their health is better or no worse than the majority's research can counteract existing stigmas and stereotypes about minorities
Scientific advances	As in the past, science might be led into unsound inferences, and unethical practices	If the causal dividend of studying race and ethnicity can be realized, important advances in population health could be achieved
Development of health services	Either as a result of faulty information or interpretation, health services may veer away from true needs	With the appropriate data services might adapt to meet needs better
Individual clinical care	Clinicians might be misled by generalities, stereotypes, and misleading research and scholarship	Armed with an understanding of ethnicity and race clinical care might become more effective
Attitudes to immigration	Adverse data on health status or health care utilization may create/perpetuate negative attitudes to immigration	By showing immigrants' contributions to healthcare delivery or the health of the nation the benefits of immigration may be clearer

to counter them. Such insights can stimulate research. While race and ethnicity are of value in clinical care, they can also lead to stereotyping, stigma, and racism. The potential value of ethnicity and race will be achieved only if understanding and application of these concepts is advanced. Some potential problems and benefits are in Table 10.5.2.

Applying the concepts of race and ethnicity: terminology and classifications to underpin data collection

Creating ethnic and racial labels, as in national censuses, is the first step to assessing a person's ethnicity, and the remaining steps depend upon the purposes of data collection. Whatever the purpose, understanding the terminology we are using, and its origins, is vital to collecting and interpreting the data. Concepts need to be simplified. In simplification, and especially in implementation, the original meaning and intent of the concepts may be unwittingly altered. To utilize the concepts of race and ethnicity as variables in population health we create population classifications. This process is pragmatic and, in the absence of firm theoretical underpinnings, it is subjective, malleable, and designed to meet perceived needs in particular populations, places, and times. The process used to devise the ethnic group question in the UK census has been particularly clearly described and provides insights that

are relevant even now (Sillitoe 1978). The process will utilize only one or a few of the facets of complex concepts. Each population subgroup needs to have a label that is both meaningful and acceptable, both to those creating and using the classification and those who are so classified. Presently, most classifications are designed for self-report of race or ethnicity, whereas in the past usually race was assigned by an official, professional, or researcher.

The value of the classification achieved, as opposed to the alternatives, should be judged by whether it serves the stated purposes. In quantitative health sciences the purpose is to establish and explain differences in health status of populations, in public health it is to improve health through prevention and control of disease, and in clinical medicine it is to make diagnosis and treatment easier. Other purposes including maintaining segregation, as in apartheid, or to perpetuate racism, though repugnant in the modern world have been important and could return, but are not pertinent to contemporary public health.

Classifications vary across times and places, reflecting both the pragmatic nature of the process of their creation and the varying purposes for which they were designed. Many complex classifications of race have been proposed. Only those relating to broad continental groupings continue to hold influence. The classification process is, inevitably, arbitrary, subjective, context specific, purpose driven, and imprecise. The process is atheoretical in that there is no coherent, valid genetic or social theory that underpins

classifications. The prime value of such classifications is in social, rather than biological, contexts and in service applications. Nonetheless, such classifications allow analysis of differences and similarities that have importance in population sciences (US Department of Health and Human Services 1985; Davey Smith et al. 2000; Bhopal 2007; WHO 2010).

As societies are becoming more racially and ethnically diverse, such classifications, despite their limitations, are in increasing use. At any one place and time, though numerous classifications are possible, one tends to dominate, with minor variants. Usually, this is the classification used in the census, or equivalent national or regional population registries in places where a census is not conducted (Sillitoe 1978; US Office of Management and Budget 1997; Bhopal 2007; Stronks et al. 2009).

The variable terminology supporting both concepts and classifications is problematic for international collaborative work. These challenges of classification, terminology, and agreement on concepts are similar to those for other complex variables such as social class and educational status—race and ethnicity are not uniquely problematic. Despite their difficulties, most classifications do work in the sense that they add to our capacity for analysis of similarities and differences in the health of populations and to take actions to improve health (WHO 2010).

Challenges of collecting and interpreting data using the concepts of ethnicity and race

The ethical justification for collecting data by race, ethnicity, and health is health improvement either directly through more informed evidence-based law, policy, or practice, or through better understanding of disease causation achieved through research. People setting up health databases and research studies need to make choices on which aspects of migration status (so often a proxy for ethnicity), race, and ethnicity are to be captured and on the method of data collection. The interpretation and utilization of the data are dependent on these choices.

Collecting data by migration status, race, or ethnicity is difficult, and requires agreement on concepts and terminology, excellent information systems, excellent communications, and understanding between data providers and data holders. There are three main approaches to assigning ethnicity and race: self-assessment, assessment by another on the basis of relevant data, and assessment by another on the basis of observation (see Box 10.5.1). The

last is not recommended. Major sources of data important to public health, which often do not have complete or valid information on race or ethnicity, include censuses, population registers, death and birth certificates, healthcare records, and disease registries. Data linkage holds great promise as a means of enriching such data sets, including the addition of race and ethnicity codes where they are absent (Johnman et al. 2012).

Data systems for monitoring the health and healthcare of multi-ethnic, multiracial populations need to be designed to record, retrieve, and analyse data on relevant variables including racial and/or ethnic group, language preference, religion, and dietary needs. The documentation for such systems should include information on the concepts underlying such variables and methods whereby the variables were collected, to allow proper interpretation by data users. The users need to interpret the data and come to valid explanations for differences and similarities, or at least valid questions that guide interpretation. A conceptual framework for interpretation of differences includes: data and system error; random error; bias in data collection; and differences in socioeconomic, lifestyle, and other cultural and genetic factors. Misinterpretation, particularly reaching unsubstantiated conclusions that differences arise from genetic factors, needs to be avoided. Definitive explanations for population subgroup differences are unlikely to be achieved, but the findings will raise questions that focus attention on priorities.

Societal responses to variations in health status by migrant status, race, and ethnicity

Generally, socially diverse societies are conscious that the health status and healthcare needs of their populations vary by migrant status, or racial or ethnic group. Once noted, such variations are not easily ignored. The responses range from merely studying the differences, blaming the minority population for their health problems and even excluding them from services, setting up special initiatives, adapting services to meet needs, and creating a general policy of equality and equity of service to meet need (Johnson 1984). The response depends on the social context and political and public views on migrants, race and ethnicity as illustrated here for the United Kingdom, United States, Australia, South Africa, the Netherlands, and Hungary.

In the United Kingdom, the health focus has been on immigrants and their descendants utilizing, primarily, the concept of ethnicity. Each group of immigrants, whether Irish, Jewish, or Indian, has been associated, rightly or wrongly, with raising the risk to the wider society of infectious diseases and environmental hazards and that kind of perception is harmful to the group. Since the 1970s there has been an appreciation of the potential value of studying variations in disease patterns, which has increased attention on ethnic minority groups. This has been followed by a policy response, backed by strong legislation, to tackle health problems seen in excess in minority groups (Johnson 1984). The 1990s and early twenty-first century have seen the rise of a social justice agenda accompanied by powerful antidiscriminatory legislation to promote equality in Britain’s multiethnic society. For legal purposes, race in its broadest sense (including ethnicity, religion, migration status etc.) has been firmly embedded within the wider equality agenda, being one of nine legally protected characteristics in the Equality Act 2010.

Box 10.5.1 Main methods of assigning migration status, race, and ethnicity

- Skin colour/physical feature
- Country of birth of self or parents/grandparents
- Name analysis
- Family origin, and ancestry or pedigree analysis
- Self-assessed ethnic or racial group
- Self-reported migration status details—length of residence, country of birth or origin, whether asylum seeker, refugee, or undocumented

Race and ethnicity classifications in the United States have been designed to help redress historical discrimination (US Office of Management and Budget 1997), and this goal remains a top political priority. In the United States attention in the field has focused on African (black) and Native American origin populations and more recently on Hispanic populations. The concept of race still dominates. Until the latter half of the twentieth century the response to racial inequality and racial discrimination was generally unsupportive or openly discriminatory. Following the civil rights movement and the Civil Rights Act 1964 the aim of narrowing the gap between the health of African Americans and white Americans has come to the fore, especially since a landmark report in 1985 (US Department of Health and Human Services 1985). This objective has not been achieved and, despite much policy analysis and interventions, inequalities have been difficult to eliminate, though this remains the goal (Sloan et al. 2010). More recently, attention has turned to a wider range of minority populations.

Australia is a country of immigrants but, surprisingly, immigrant health, ethnicity and race have not loomed large in the health response. Rather, the focus has been on the indigenous populations, especially the Aborigines (Hill et al. 2007). The late twentieth century saw an awakening to the appalling health and health services they have and a resolve to improve matters. Efforts to date have paid little dividend in terms of narrowing inequality. However, the rising population size of Aborigines following a near catastrophic decline in the nineteenth century signals improvement, that is, that death rates are reducing, which is true in absolute terms though not relative to the whole population, and are lower than birth rates. This challenge has implications for the worldwide indigenous populations (see Chapter 10.6).

South Africa under apartheid (1948–1994) exemplified the damaging effects of promoting separate development for different racial groups, the results being excellent health, well-being and service for the country's white population compared to the other groups, especially the black African majority. Vigorous efforts are being made to redress these injustices in post-apartheid South Africa but there is ambivalence about the continued value of using race and ethnicity in this context. As in the United States, however, it is problematic to resolve problems caused by racism, without using the concept to tackle the resulting problems, although the whole area is embroiled in controversy (Ellison and de Wet 1997).

The Netherlands became one of the world's most diverse multi-ethnic societies in the late twentieth century. It institutionalized the use of country of birth as the primary, proxy measure of ethnicity (Stronks et al. 2009). Its policy response has been unstable in the light of political change. The current attitude is that while special efforts may be required for the foreign-born, rapid integration and assimilation should occur such that the descendants of migrants ought to require no special services. Research in the Netherlands is advanced, including the development of major cohort studies (Dekker et al. 2011).

Hungary is a country that has had a tumultuous history, and is currently transforming itself into a modern European state. One of its great challenges is to translate the ideal of equality—enshrined in its constitution and laws—in relation to its sizeable Roma (Gypsy) population (Ministry of Foreign Affairs Budapest 2004). This ethnic minority group, though nomadic by tradition, has been settled in Hungary for centuries, some people tracing

their roots in and around Hungary back to the fourteenth or fifteenth century. The Roma population is, comparative to the population as a whole, very poor, with low levels of education and employment, and a multiplicity of health challenges, including a life expectancy 10 years lower than non-Roma. The vision in Hungary is a grand one and the result is of the greatest significance for Europe as a multi-ethnic continent.

The variety of responses in these countries is striking. Nonetheless, some pattern is discernible: first comes an awareness of health problems and especially of a risk of infectious disease harming society as a whole; second comes the formal study of health status and healthcare by migrant status, ethnic or racial group; third there is articulation of policy and plans sometimes backed by legislation; fourth we see a move from policies of exclusion of minorities to the promotion of the welfare of minorities; fifth there are specific actions to redress inequities; and, finally, there is an attempt to adapt general services to meet needs. The scale of the public health challenge is great and none of the six countries considered here has yet achieved the goal of substantially and sustainably narrowing health inequalities or achieving equity of service.

Spurred by rising global and national movements for universal human rights in the late twentieth century, and a realization that immigration is vital to their economic and demographic health, many countries are changing their stance, with equity of health status and healthcare being a central focus (WHO 2010).

Data on race and ethnic group have both harmed and benefited minority populations, and will continue to do so, yet without the data the need for services cannot be established. Data need to be collected within international ethical and legal frameworks that safeguard the human rights of minority and majority populations alike (International Organization for Migration (IOM) 2009). The goals of equality and equity, and monitoring of progress towards the goals, cannot be achieved without data on migration status, race, or ethnicity, as recognized by the WHO in 1983 (Colledge et al. 1983) and re-emphasized in the WHO's and IOM's global consultation (WHO 2010).

Assessing health and healthcare needs of racial and ethnic minorities using quantitative and qualitative data

A health needs assessment is an overview of quantitative and qualitative data on a population or subgroup of the population (see Chapter 11.1). Its purpose is to help improve population health and healthcare. Health needs assessment in racial and ethnic minority groups is sometimes problematic for lack of comparable and high-quality data, particularly at local and international levels, and at the level of subgroup detail required (Rafnsson and Bhopal 2009). At the local level it is often limited to qualitative studies or consultations. For national studies data from administrative databases utilizing broad racial or ethnic categories or proxies such as country of birth may need to be used (Stronks et al. 2009). The limitations of such data need to be understood to reduce the risk of making poor decisions.

Needs assessment for minority populations starts by examining the health status, disease patterns, and healthcare utilization within each group. This is the absolute risk approach (Bhopal 2007, 2008).

The findings are then compared with other minority and majority groups. In most instances the standard comparison is with the white (European origin) population as a whole, even although this may contain within it subgroups that may be as disadvantaged as the non-white groups under study. This is done either for ease, habit, ethnocentrism, limited availability of data, the policy and political leverage of the approach, or statistical power (Bhopal 2007). An alternative approach, but rarely used, is to set the comparison against the group with the most desirable level of the health indicator under study. These comparative approaches comprise the relative risk approach (Bhopal 2008). Qualitative data enrich and help validate the quantitative analysis by giving needs assessors access to opinions, perceptions, beliefs, attitudes, self-reported behaviour, and case histories (Bandesha and Litva 2005; Bhopal 2007).

Health needs assessments (Gill et al. 2007) have shown that commonly held views on the needs of minorities are often erroneous, for example, levels of immunization are sometimes high not low (Baker et al. 2011), life expectancy may be greater than in the population as a whole, and health education materials may bear little relation to disease patterns and so on (Bhopal 1988). Some generalizations hold: health needs vary substantially by group; minority groups are better off in health status and even healthcare in some respects and worse off in others; service quality, including for preventive health issues and face-to-face communications, is usually worse for minority groups; and needs as articulated by minority groups in consultations and qualitative research mostly focus on communication, information, religious requirements, dietary preferences, and informed consent (Gill et al. 2007). Since health needs assessment is an intensive and costly process, and not always achievable, some principles are important as follows (Bhopal 2007):

1. Avoid the piecemeal approach to tackling minority health needs whereby so-called race- or ethnic-specific topics are tackled one by one. A balanced overview is needed (Gill et al. 2007).
2. Base the needs assessment on ranks of causes using case numbers and disease rates (Table 10.5.3).
3. Refine understanding by looking at comparative indices, which will focus attention on inequalities and inequities (Table 10.5.3).
4. Interpret the quantitative data in the light of the qualitative findings.
5. Draw with care, and with due emphasis on social and economic deprivation as explanatory factors, causal hypotheses based on differences.
6. Beware that inferences of biological differences between groups may be particularly prone to error and misinterpretation, and may harm the standing of minority groups.
7. Make a judgement, preferably in consultation with minority populations concerned, on how the data can be best used to improve the health and healthcare of the population, majority and minority groups alike.

8. Minority ethnic groups must not be excluded from, or inhibited from, using major public health and healthcare initiatives, even if segregated or special services are set up. There is an important but unanswered question of whether people who do not belong to particular ethnic groups can be excluded from special services set up for a particular group. I believe this could be indefensible in law and on ethical grounds, especially if a person from another ethnic group could demonstrate an equal need for such services.
9. The needs of minority groups should be met simultaneously with the rest of the population, not deferred until some later date to be handled as a separate matter.
10. All public health policies and plans should make explicit how the needs of minority groups are to be met.

Inequalities, inequities, and disparities in health and healthcare by race and ethnicity

Health status, disease occurrence, and mortality patterns in populations are sculpted by factors such as wealth, environmental quality, diet, behaviour, and genetic inheritance (Box 10.5.2) (Nazroo 1998; Davey Smith et al. 2000; Krieger 2002). Most of these factors are directly or indirectly related to ethnicity and/or race, therefore, it is unsurprising that there are stark health inequalities by race and ethnicity. The questions of interest are why they occur and what needs to be done to narrow them. Specific health inequalities are likely to have their own causes. For example, ethnic inequalities in risk of skin cancers such as melanoma are likely to have a biological basis relating to skin pigmentation, while inequalities in stroke need to take account of many factors, including healthcare, cultural, economic, and biological matters over the life course.

The concept of inequity, as opposed to inequality, is central to policy and strategy. Inequity implies an inequality that is unfair or unjust (disparity is the equivalent word in the US context), for example, those arising from inadequate access to knowledge or services, and these form a primary target for action, particularly if effective interventions are available. Other inequalities, for example, the differences in the rate of skin cancer, are not unjust. They pose, nonetheless, a major challenge to understanding and a focus for both science and services.

Inequalities are demonstrable using virtually all classifications of migration status (see Chapter 10.9), race, and ethnicity, and are usually sharpened by taking account of population heterogeneity and examining men and women separately. The differences between such groups are often large, particularly for specific conditions, for example, diabetes, stroke, and bowel cancer, and less so for general measures of health, for example, life expectancy. Even where such inequalities have been carefully studied and actions to reverse them are proposed, mostly they have not

Table 10.5.3 The standard table for assessment of the pattern of disease, particularly for needs assessment purposes

Disease or condition	Number of cases	Rate	Rank position on number of cases or rate	SMR/relative risk	Rank on SMR

Box 10.5.2 Major factors generating or influencing health inequalities by migrant status, race, or ethnicity

- ◆ Culture, for example, taboos on tobacco, alcohol, contraception, etc., many of them generated by religious and spiritual beliefs that differ between populations.
- ◆ Social, educational, and economic status, for example, knowledge of biology and causes of ill health, languages spoken and read, qualifications that are recognized, and occupational opportunities.
- ◆ Environment before and after migration, for example, climate, housing, air quality, etc.
- ◆ Lifestyle, for example, behaviours in relation to exercise, alcohol, diet.
- ◆ Accessing, and concordance with, healthcare advice, for example, willingness to seek social and health services and adhere to advice, and use of ‘complementary/alternative’ methods of care including the health systems of the country or origin.
- ◆ Genetic and biological factors, for example, birth weight, growth trajectory, body composition, genetic traits and diseases, etc.

Reproduced from Raj. S Bhopal, *Ethnicity, Race, and Health in Multicultural Societies*, Second Edition, Table 6.1, p. 165, Oxford University Press, Oxford, UK, Copyright © 2014 Raj. S Bhopal, by permission of Oxford University Press.

been greatly narrowed and sometimes they have widened. Ethnic group inequalities could help set new more demanding targets, for example, in many countries in Europe, North America, and Australia the target for coronary heart disease mortality could be set as the low rate in the Chinese population (Nijjar et al. 2010), and that for bowel cancer as the South Asian population’s low rate (Bhopal et al. 2012). One of the dilemmas is the choice of which of the many inequalities to tackle, and this requires principles.

Principles for setting priorities for the health and healthcare of racial and ethnic minority populations

Priority setting is a process for making rational choices from multiple alternatives (see Chapter 3.5). The public health sciences, particularly epidemiology, can underpin priority setting, which follows from the process of health needs assessment. Quantitative and qualitative data on health status and service utilization are often available (though they may be crude). In contrast, relevant information on cost and effectiveness of interventions is rarely available, posing a formidable challenge (Bhopal 2007).

Priority setting benefits from principles, for example, that the priorities are those actions that maximally benefit the health of a population or subpopulation. Another principle is that because similarities between human populations tend to outweigh differences, the priorities of general society are of great importance to racial and ethnic minority groups. These general priorities, however, are necessary but not sufficient. They need adjustment on the

basis of health needs assessment. For long-settled communities, and minorities born or raised in the country, the adjustments may be modest or even minor. For others, such as those who do not speak the local language, or those suffering racial discrimination, the adjustments needed may be substantial. Reductions of inequalities and inequities (disparities), however, can only be achieved if health improvement occurs fastest in the most disadvantaged population—and getting the priorities wrong can widen inequalities (Bhopal 2007).

All healthcare and public health policies and plans should make explicit what the priorities are, whether they are different for different groups, and how the needs of minority groups are to be met. Evaluation of services and audit of quality of care providing evidence that the quality of care for minority populations is not equitable is particularly effective in bringing about change, as it goes against international and national policies and laws promoting equality.

Policy and strategy to improve health and healthcare for racial and ethnic minority groups

Health services for minority groups are usually set within the policies and strategies for the population as a whole, in practice the majority (or most powerful) population. Ideally, policies for the whole population would address the needs of minority groups in an integrated way. This concept is known as mainstreaming (Bhopal 2007). In practice this may not happen for reasons including absence of understanding or agreement that this is important, the complexity of the issues raised and lack of expertise, time, and publication space within policy and strategy documents. Mostly, minority populations are expected to adapt themselves to benefit from the available services. Professionals delivering the service tend to make some adjustments on an ad hoc basis. Increasingly, we see two further policy responses—setting up specialist services for minority groups but within the main service, and the development of strategies to help re-shape existing services to meet needs. The complete separation of services for minorities is currently not in favour. Here, I consider briefly the policy response in the United Kingdom and the United States.

The UK policy response until about 1990 was intermittent and fragmented, with a mixture of stand-alone projects and modifications to mainline services. Progress has been made on key requirements such as interpretation services and dietary needs in hospital (Gill et al. 2007). The Race Relations Amendment Act 2000 building on the 1976 Act, coupled with explicit or implicit policies from the government health departments, drove more widespread changes based on a positive duty to promote racial equality (The Home Office 2001). These national initiatives affect everyone and are being translated, often with great difficulty, into local action plans and ultimately service changes. The work on race and ethnicity was incorporated within the wider equality agenda in the Equality Act 2010.

The United States has had a long-standing programme for affirmative action based on human rights principles that aims to redress historical wrongs (US Department of Health and Human Services 1985). Its racial and ethnic classification is explicitly designed to help achieve this goal (US Office of Management and

Budget 1997). The pluralistic nature of the healthcare system of the United States, based on private healthcare principles, makes a cohesive strategy impossible to enact nationally but huge progress is being made, with global leadership, especially in research (National Institutes of Health and US Department of Health and Human Services 2012).

While many policies, strategies, and action projects exist, health services internationally have struggled with the challenge of equitable healthcare in multicultural societies. These struggles are especially seen in relation to undocumented migrants (see Chapter 10.9), indigenous populations (see Chapter 10.6), and long-established but still culturally and socially distinct populations such as Roma. Current opinion favours mainstreaming with adaptation of general existing services, and incorporation of minorities' needs into the design of new services. These ideals are constrained by lack of funds, expertise, data, and the ongoing political controversies around immigration, asylum, race equality, and human rights. While policy, strategy, and action is highly dependent on local context, some of the principles, experience, and lessons are transferable internationally.

To date the challenges have been tackled mostly at the level of structure and process—what systems might work and what should we do? Equity in service delivery is increasingly the central focus, with outcomes in terms of healthcare delivery and its quality as the benchmark. The achievement of outcomes measured in terms of health status is seldom the centrepiece of discussion, although the United States has recently moved to this (Warnecke et al. 2008). This is currently too great a challenge for most countries, not least because the causes of health status differences are often not clear. Even conceptually, it is difficult to set a benchmark. What would be the goal? Racial and ethnic inequalities and inequities in health and healthcare are far more complex than socioeconomic inequalities, not least because socioeconomic factors are part of them. Racial and ethnic inequalities are very hard to predict and vary by cause of ill health and by risk factor and are rapidly changing. The importance of the wider determinants of health such as wealth, housing, employment, and education for minority groups is, however, clear. Policies and strategies to achieve better health for minorities are strengthened and sustained by their incorporation within a broader agenda for social justice and civil rights, and within wider policies to reduce inequalities.

Race equality impact assessment methods are being developed. These are being applied to a wide range of policies, for example, transport, health and safety, and employment practices. In this way there is an interconnection, and synergy, across the different sectors of social life. Effective responses are constrained by lack of funds, expertise, data (particularly on what works and why), and the ongoing political controversies (usually negative in tone) around immigration, asylum, race equality, and human rights. Policies are most powerful and effective when they are supported by a coherent legal and ethical framework. The framework, of necessity, reflects the values of the society and particularly those of politicians.

Research on and with racial and ethnic minority groups

Research utilizing race and ethnicity influences society and will be interpreted to meet social goals. Just as modern-day work is

mostly used to further current goals of social equality and justice, so it was that much research in the past was used to further previous social and political goals such as the continuation of slavery, the justification of Empire, the maintenance of social and material inequality (including apartheid), anti-immigration policies focused on those who were not Northern Europeans, eugenics, and the Nazi genocides (Bhopal 2007). The most important lesson from this history is that this research on racial and ethnic minorities needs to be done within an ethical framework emphasizing benefit to the population studied primarily, and to wider society secondarily. Researchers are developing consensus statements on how to achieve this (Mir et al. 2013).

The full range of health sciences and their methodological approaches—literature review, qualitative studies, case-histories, case series, laboratory research, analysis of routine statistics, case-control studies, cohort studies, trials—are potentially applicable to race, ethnicity, and health research. An explosion of research on the genetic and environmental basis of ethnic/racial variations is underway as virtually all societies become multi-ethnic ones through migration (Afshari and Bhopal 2010).

Researchers need to make explicit how they are using ethnicity and race for, and adapting their classifications and methods to, the research questions under study. Researchers should not always be constrained by available classifications designed for administrative purposes though veering from them should be done thoughtfully. Researchers who are knowledgeable about the minority groups under study are more likely to be trusted and more likely to achieve the high response rates and informed consent that are essential, and also to interpret data with minimal error and bias. In writing up and publishing their work, researchers should minimize the danger of harm to the groups studied, particularly, the stigma which can ensue from associating them with problems for healthcare systems. Overemphasis of health problems, especially when imbalanced, can lead to stereotyping and fuel racism.

The ideal population research study would be inclusive of all minority groups, have uniformly high response rates, provide data that are comparable across all groups, collect information on all relevant facets of race and ethnicity, include data on all potential confounding variables, and be analysed and interpreted in a way that advances science, improves health status, and develops better healthcare. In practice, many ideals are sacrificed to make studies feasible. In making pragmatic choices, researchers should make themselves and others aware of the limitations of the work.

The challenge of race, ethnicity, and health research includes demonstrating tangible health benefits in addition to satisfying curiosity and extending the boundaries of knowledge. Minority health is a beguiling research theme for it often focuses on underprivileged groups; it is interesting and often unearths unusual results; differences between groups can be demonstrated with ease; and even small studies can yield robust, significant and relevant results.

There are numerous challenges in epidemiology of race and ethnicity—see Box 10.5.3. There are others relating to other social, population, and medical sciences. One of the greatest overall challenges is doing good work in the light of inherent complexity and amidst criticism. Researchers are left with the decision to either avoid the controversy and difficulty associated with race and ethnicity variables (an action which may be socially, politically,

Box 10.5.3 Some challenges for epidemiological research on ethnicity, race, and health

- ◆ Inclusion of minorities in research and analysis of data by migrant status, race, or ethnicity.
- ◆ Clarification of the purpose of the research.
- ◆ Definitions of concepts relating to migration status, ethnicity, and race that are internationally agreed.
- ◆ Definition and precision of terms, and migrant group/ethnic/racial classifications and clarification on how they have been used.
- ◆ Recognition of heterogeneity within minority and majority groups alike.
- ◆ Identification of representative populations.
- ◆ Ensuring comparability of populations that are to be compared, requiring especially socioeconomic data over the life course to show this.
- ◆ Avoiding misinterpretation of differences that are due to confounding variables.
- ◆ Accurate measurement of the denominators and numerators in calculating rates.
- ◆ Ensuring the quality of data, particularly in cross-cultural comparability.
- ◆ Maximizing completeness of data collection.
- ◆ Pinpointing specific genetic basis of genetic hypotheses.
- ◆ Properly argued interpretation of associations as causal or non-causal.
- ◆ Maximizing validity and generalizability of the research.
- ◆ Presentation of research to achieve benefits for the population studied, and avoid stigmatization and racism.
- ◆ Appropriate action to follow the research that, ideally, benefits the entire population.

Reproduced from Raj S. Bhopal, Glossary of terms relating to ethnicity and race for reflection and debate, *Journal of Epidemiological Community Health*, Volume 58, Issue 6, pp. 441–45, Copyright © 2004, with permission from the BMJ Publishing Group Ltd.

legally, and scientifically unacceptable) or to do their best, with the express intention of continually improving their work.

There is still massive potential for causal understanding through the in-depth investigation and explanation of racial and ethnic variations—see Table 10.5.4 for an example of the approach

needed. The huge potential of research on racial and ethnic minorities for service planning and delivery also needs good design and a clear focus, better data, and experience of putting research to use. Improvements will come from conceptual openness, explicit and defined terminology, and imaginative solutions

Table 10.5.4 Categorizing and analysing the factors which may underlie an epidemiological variable: the example of stroke

Category of potential explanatory underlying difference	Example of possible specific differences by migrant status, race or ethnic group	Implications for data collection
Biological	Unique variants of human genes, or varying frequencies of such variants (polymorphisms) lead to different biochemistry or physiology	Collect biological data including DNA, blood, and other tissues
Co-existing diseases	One group may have more or less of another disease which raises or reduces the risk of stroke disease, e.g. diabetes	Collect clinical data, including appropriate diagnostic tests
Behavioural	One group may eat more fruits, vegetable, and salads than another, and perhaps smoke less	Collect data on behaviours relating to health
Social	Members of a group may spend less time with friends and family, and other social networks, so increasing psychosocial strain	Collect psychosocial data as potential explanations
Occupational	The pattern of working, including likelihood of employment, the hours worked, and the type of occupations is substantially different	Collect data on employment histories
Economic	Members of a group may earn less than the average or have varying amounts of accumulated family wealth	Collect data on differences in income and wealth and their effect on lifestyles and stress
Healthcare	Members of a group may be treated differently from the expected standard by healthcare professionals	Collect data on quality, quantity and timing of healthcare interventions

to the fundamental issues such as matching denominators and numerators, representativeness of the population, comparability of subgroups, and validity of the measurement tools.

For many causes, morbidity and mortality rates are lower in minorities but these gain little attention. The perception that the health of minority groups is poor can augment the belief that immigrants and racial or ethnic minorities are a burden. The perception of poorer health arises from a focus on those differences where the excess of disease is in the minority population. It is naïve to believe that the mere demonstration of inequalities by migration status, race, or ethnicity will narrow them and it is plausible that such studies can perpetuate and even augment inequalities. The study of racism is important but relatively neglected (Afshari and Bhopal 2010). Racism, undoubtedly, is a difficult subject to study in the health arena, but there is also a reluctance to take it on, though less so in the United States than in other places including Europe (Parker 1997; Krieger et al. 2010).

The promise of causal understanding has meant a focus on variation in diseases, as opposed to the quality of services. So there is a gap in the research record on the quality of care received by minority groups, to the detriment of the services and populations served. Minority populations are seriously under-represented in major studies, especially cohort studies (Ranganathan and Bhopal 2006) and trials (Geller et al. 2011).

Conclusions: theoretical, ethical, and future-orientated perspectives on health, race, and ethnicity

Used responsibly, race and ethnicity have the potential to improve public health, healthcare, clinical care, and medical science (Gill et al. 2007; Tobias et al. 2009) but used unwisely they can do immense damage (Kohn 1995). Stringent attention to underlying theory and the principles of ethics and justice is essential as the primary safeguard against harm. There is no single theory (or group of theories) on race and ethnicity and health that is widely accepted or applied. Biological theories based on species and subspecies have not withstood testing and social theories have not yet been articulated in a way that has made a major impact in medical sciences. Advances in the science of genetics are reopening old debates on the biological underpinnings of racial and ethnic differences. Articulating coherent and useful theories on migration, race, and ethnicity in the health domain is a continuing challenge. Migration status, race, and ethnicity conform, and contribute, to the general epidemiological theories on the forces that shape population differences in health status and hence they are important in public health and healthcare.

A rational, analytic approach to the interpretation of data, set within broader epidemiological theories of health, is needed. Interventions utilizing race and ethnicity need to be carefully evaluated to judge the likely balance of benefits to costs. In a political environment where anti-immigration sentiment is high and encouraged, the use of race and ethnicity indicators may be counterproductive. There is an imperative to achieve benefits in terms of health improvement and to demonstrate this unequivocally.

Public health and medical care are humanitarian disciplines that are focused on the most needy (the at-risk or already sick) who are often also the most economically disadvantaged. The key

to doing good is a social and cultural milieu of equality/equity/non-discrimination. Given this, the thoughtful application of the approaches of the social and population health sciences to race and ethnicity should yield workable classifications and data that can be interpreted using epidemiological frameworks for analysis. The analysis arising can feed into needs assessment, priority setting, the inequalities debate, policy- and strategy-making, and scholarship and research. There is a virtuous cycle around data—the more it is used the more the enthusiasm for its collection and for improvement in data systems. Data also improves services both directly (through better decisions) and through the motivating effects of monitoring and evaluation in improving performance. Race and ethnicity are important concepts and variables in epidemiology and public health.

The health of indigenous peoples

Ian Anderson and Sue Crengle

Indigenous peoples: a contested concept

People who are described as indigenous, or who describe themselves as such, are found in nearly all regions of the world. They include San and Pygmy peoples in Africa; Australian Aboriginal, Māori, and other Polynesian peoples of the Pacific; and distinct peoples across Asia and the Indian subcontinent, circumpolar regions, and the Americas. They have a range of social, cultural, and political characteristics, and nearly all contemporary commentators note the difficulty in developing a definition of 'indigenous' that satisfactorily embraces the full range of these contexts (Stamatopoulou 1994; Kingsbury 1998; Niezen 2003; Coates 2004; Stephens et al. 2005). This debate is not just academic. The contested nature of indigenous identities has significance within and between indigenous communities—where it is often a marker of insider and outsider status (Weaver 2001). Further, legal and political ramifications of these definitions impact on access to resources, land title, and recognition of rights.

Who decides these matters? There is tension between the rights of people to represent themselves (self-identification) and international bodies (which are entangled in these debates, have distinct interests, and may ascribe a social identity not acceptable to the peoples in question). However, debates that have occurred as nation states or international bodies have engaged with this problem demonstrate both the challenge of agreeing on a definition and the cultural, intercultural, political, geographic, and historical dimensions of this concept.

Arguably, the ambiguity is less where there has been a distinct population, such as the first-recorded human inhabitants of regions such as Australia, New Zealand, and the Americas, and a defined historical moment in which external powers colonized these regions, dispossessed peoples, developed legal original inhabitants, and maintain political and social distinction between native peoples and settlers (Stephens et al. 2006). In other contexts, such as Asia, Africa, and the Middle East, distinctions are less clear with multilayered histories of colonization between and within countries. In India, for example, social hierarchies created categories in which social position is established at birth with some groups designated as tribal or indigenous on a sociocultural basis (Stephens et al. 2006). In Africa the idea of indigenous is highly contested. Many would claim all Africans are indigenous in relation to European colonization. However, groups such as the

San or Pygmy people claim indigenous status notwithstanding this colonial history, having a history of colonization by African peoples prior to Europeans (Stephens et al. 2006).

These definitional debates echo through public health. *The Lancet* published a series of papers in 2006 on indigenous health across the globe. A year earlier, it published an introductory commentary to the series, which argued that, despite the aims of the United Nations International Decade of the World's Indigenous Peoples, 'little had been achieved [in] strengthening international cooperation for the solution of problems faced by indigenous people in such areas as human rights, the environment, development, education, and health' (Stephens et al. 2005). Anthropologist Adam Kuper wrote to the journal arguing that it should not proceed with the proposed series, as 'indigenous' is commonly used as a euphemism for 'primitive', and not only was the term difficult to define, it was also difficult to identify who is indigenous given the complex historical layers of migration, intermarriage, and linguistic and cultural change. These problems, Kuper argued, become even more 'acute and embarrassing, when it comes to determining who should be accepted as being a genuinely indigenous person' (Kuper 2005, p. 983). Following the publication of the series, he argued that it was dangerous to presume that health problems were inherent to peoples' indigenous status, nor were health inequalities limited to populations labelled as indigenous (Kuper 2007). Some papers in the series engaged with the definitional challenges (Kingsbury 1998; Niezen 2003; Stephens et al. 2005, 2006; Anderson et al. 2006; Montenegro and Stephens 2006; Ohenjo et al. 2006), but also documented patterns of poorer health and health inequalities compared to benchmark non-indigenous populations. The inference that health inequalities are inherent to indigenous status is arguably not the focus of public health thinking on indigenous health. The dominant paradigm today is much more closely aligned to public health models that have emerged out of thinking in relation to the social determinants of health, which have been used in the analysis of patterns of health inequality in other populations (Carson et al. 2007; Mowbray 2007).

Despite these debates, since the 1970s the concept of indigenous peoples has attained a significant status and has been 'a basis for group mobilization, international standard setting, transnational networks and programmatic activity of intergovernmental and nongovernmental organizations' (Kingsbury 1998, p. 414).

Cultural and political frameworks

There are two broad approaches to the academic construction of indigeneity: one is cultural, the other political (Coates 2004). The cultural framework emphasizes cultural characteristics of indigenous people and contrasts them with urban capitalist societies. The political model emphasizes political characteristics and political and social relationships with settler societies. Although this definitional debate presents a challenge, Niezen argues that ‘a rigorous definition... would be premature and, ultimately, futile... there are multiple approaches to the term “indigenous” each with its own political origins and implications’ (Niezen 2003, p. 19).

The classic cultural model of indigenous peoples is described as a small-scale society, who live by more traditional local modes of economic productions such as hunting and gathering, herding or non-intensive forms of subsistence agriculture. In the culture of these societies there is a strong emphasis on kinship relationship and local forms of political organization (O’Neil 2009). Perhaps some archetypal examples can easily be characterized as small scale—Aboriginal Australians and southern African San peoples—but this approach has inherent problems. Although it may be historically accurate to characterize social circumstances of some indigenous peoples as small scale, this is not so for peoples such as descendants of the Mayan and Incan civilizations in central and South America. It also fails to account for historical transformations of indigenous populations that are, no matter how remote, increasingly connected to global cultural and economic processes. Many indigenous populations are urbanized and integrated within capitalist economies—even though they may maintain traditional economic practices and occupy relatively marginal positions within the broader economy. For some, such as Australian Aboriginal people in remote central and northern regions, the transition has been from a subsistence economy to the welfare economy. In Guyana, indigenous peoples (Amerindians) constitute 9.2% of the population, are mainly outside the cash economy, and are disproportionately among the poorest people in the country, which ranked 104 of 177 countries in the Human Development Index (HDI) (Hartley 2008; Nogkynrih 2008).

San is a collective name for indigenous peoples of southern Africa with a connection to the region dating back 27,000 years. They lived a hunter-gather lifestyle until the late twentieth century, but most now live sedentary lifestyles. Although they maintain a social and cultural distinctiveness, their culture and economic mode of production has changed. Cultural change notwithstanding, indigenous peoples may respond to social trends and cultural change in a distinct way from the dominant society. This includes the adoption or transformation of cultural forms such as musical styles or particular responses to cash economies. Some cultural change may be resisted, but indigenous peoples may also readily engage with forms of development such as mining or farming. Many retain distinct identities and cultural practices in the face of dispossession and social marginalization, and a sense of connection to a pre-colonial past.

The political framework commonly emphasizes minority status. This is true for indigenous populations such as the Ainu of Japan and Canadian Aboriginal and Native America communities. Contemporary political circumstances of indigenous peoples are shaped by their dispossession from traditional lands and natural resources and incorporation within institutional and political

structures of settler states. The management of indigenous peoples by settler states has often involved legal frameworks, policies, and administrative structures, and the rights of indigenous peoples and those of settler majorities are frequently differentiated. This pattern of political disempowerment is reflected in other forms of social and cultural marginalization.

The minority status of indigenous peoples figures prominently in how they are framed within some jurisdictions. In the Russian federation, for instance, people recognized officially as indigenous are the ‘numerically small indigenous peoples of the North, Siberia and the Far-East’ (Donato n.d.). There are 44 such groups with a total population of 250,000 people, and their cultural, territorial, and political rights are enshrined through the constitution and national legislation. But not all indigenous populations are demographic minorities. The indigenous people of Fiji have a dominant political status, and the indigenous population of Bolivia is also in the majority (Montenegro and Stephens 2006).

Debates about the cultural construction of indigeneity echo debates about ethnicity as a construct in health analysis. Ethnicity has, for example, been defined as ‘voluntaristic self-identification with a group culture’ (Bradby 2012, p. 955). In the North American literature—where racial categories are prominent in official discourse and frequently used in administrative data collections—the conceptual distinction between ethnicity and race is particularly germane. Although race is generally now recognized as socially constructed categories ‘established hundreds of years ago to divide humans into five major subpopulations’ (Ford and Harawa 2010, p. 252) (largely on the basis of differences in appearance), there is still a tendency to slip into the biological essentialism that locates the social characteristics of distinct populations. Perhaps the distinction to be made is that indigeneity implies a social stratification that has emerged historically in relation to colonial processes resulting in a differentiation of the civic status of indigenous peoples compared with settler populations. Ford and Harawa propose a definition of ethnicity that encompasses this formulation: ethnicity is a ‘two-dimensional, context-specific, social construct with an attributional dimension that describes group characteristics... and a relationship dimension that indexes a group’s location within a social hierarchy’ (Ford and Harawa 2010, p. 251). This approach integrates cultural and political frameworks without falling into the pitfalls of a cultural essentialism that disallows either cultural diversity or change. However, it only works if colonialism—and responses to it—is conceptualized as a significant process in the production of social stratification.

Policy and law

Over the past few decades, debates on the rights of indigenous peoples have focused on recognition of indigenous peoples and the consequent rights that flow from this. This has been influenced by the broader human rights movement, as well as by indigenous-led political movements. Local political movements that resulted in indigenous land rights in nation states such as Australia, Canada, Norway, and Sweden have been in turn influenced by transnational politics.

These developments have had a long genesis. The International Labour Organization (ILO) started working on indigenous issues when it operated within the League of Nations prior to the Second World War. However, it was unable to draw attention to these

issues until, under the League's successor, the United Nations, it developed a draft protocol, which later formed the basis of the 1957 ILO Convention 107, which offered directives to governments responsible for indigenous populations. Article 1, ILO Convention 169, ratified in 1989, defined indigenous peoples as:

(a) Tribal people in independent countries whose social, cultural and economic conditions distinguish them from other sections of the national community and whose status is regulated wholly or partially by their own customs or traditions or by special laws or regulations

(b) Peoples in independent countries who are regarded as indigenous on account of their descent from the populations which inhabited the country, or a geographical region to which the country belongs, at the time of conquest or colonization or the establishment of present state boundaries and who irrespective of their legal status, retain some or all of their own social, economic, cultural and political institutions. (Department of Economic and Social Affairs 2004)

The development of an agreed definition of indigenous peoples with global application has been a significant focus of international processes (Department of Economic and Social Affairs 2004). The ILO definition is commonly cited, as is the working definition developed in 1972 by a United Nations study:

Indigenous communities, peoples and nations are those which, having a historical continuity with pre-invasion and pre-colonial societies that developed on their territories, consider themselves distinct from other sectors of the societies now prevailing in those territories, or parts of them. (Coates 2004, p. 6).

The substantive focus of these global movements coalesced around issues of rights. In 1985 the United Nations Working Group on Indigenous Populations began drafting the United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP), often described as the most comprehensive statement of the rights of indigenous peoples. On 13 September 2007 the United Nations Assembly adopted the UNDRIP with an overwhelming majority of 143 votes (with only four negative votes (Canada, Australia, New Zealand, and the United States) and 11 abstentions) (International Work Group for Indigenous Affairs 2007). Those nation states that voted in the negative subsequently reversed their opposition. The United States was the last to do so, when, in 2010, President Obama announced his government's intention to support the Declaration, noting that 'What matters far more than words—what matters far more than any resolution or declaration—are actions to match those words' (White House Tribal Nations Conference 2011). Les Malzer, Chair of the Global International Indigenous Peoples' Caucus, noted that:

The Declaration does not represent solely the viewpoint of the United Nations, nor does it represent solely the viewpoint of the Indigenous Peoples. It is a Declaration which combines our views and interests and which sets the framework for the future. It is a tool for peace and justice, based upon mutual recognition and mutual respect. (Malezer 2007)

The UNDRIP also has indigenous critics. Some argue it is framed by colonial and gendered assumptions and question its potential as a tool for addressing indigenous disadvantage (Watson 2011). Protracted arguments during its development included a dispute about whether the appropriate terminology should be 'indigenous peoples', 'indigenous people', or 'indigenous populations'. The contestation of such apparently trivial distinctions was pursued by some governments which opposed the use of the first construct

on the basis that it inferred collective rights (Niezen 2003). Other governments denied the existence of indigenous peoples within their jurisdictions (despite, in some cases, strong support for indigenous rights in other contexts), as seen in comments sent in 1995 from the People's Republic of China to a working group of the United Nations Commission on Human Rights:

Although there is no indigenous peoples' question in China, the Chinese Government and people have every sympathy with indigenous peoples' historical woes and historical plight. (Kingsbury 1998, pp. 417–418)

In Myanmar, which has a population of 50 million with 68% coming from one ethnic group, the other 'ethnic nationalities' are usually considered Myanmar's indigenous peoples in international fora (Hartley 2008). In Thailand, indigenous peoples are commonly referred to as tribal peoples or ethnic minorities. There are fisher peoples to the south and highland peoples spread across 20 provinces in the north and north-west, and nine groups ('hill tribes') in the highlands are recognized by the government. Some reluctance, by some Asian nations, to recognize indigenous populations has shifted over time. In 2008 the Japanese parliament recognized the Ainu as the indigenous people of northern Japan and noted that Japan was not culturally homogeneous and that Ainu have a distinct language, religion, and culture (United Nations Permanent Forum on Indigenous Issues n.d.).

The ways in which indigenous peoples have been treated within constitutional and legislative structures of nation states reflect colonial history, the cultural legacy of settler peoples, and the further development of political structures and institutions in these nation states. Legal and policy definitions applied to indigenous peoples have impacted on the allocation of resources, access to services, and the realization of rights. Some jurisdictions have treaties between settler and indigenous peoples (Kunitz 1994). Others, such as Australia, have constitutional and legislative frameworks that define and regulate indigenous peoples (Anderson and Whyte 2006). Others do not formally recognize indigenous peoples. These contexts are important in understanding the development of policy and programme responses to indigenous health needs.

The original Australian constitution had two 'race' clauses. Their interpretation is contested, but after a 1967 referendum resulted in their deletion, the Commonwealth government began to become directly involved in indigenous policy and programme development (Chesterman and Galligan 1997). In 1981, the Constitutional Section of the Department of Aboriginal Affairs proposed that 'An Aboriginal or Torres Strait Islander is a person of Aboriginal or Torres Strait Islander descent who identifies as an Aboriginal or Torres Strait Islander and is accepted as such by the community in which he (she) lives' (Gardiner-Garden 2000, p. 4). This became the basis of the 'working definition' of Aboriginality and has been used in determining eligibility in administrative processes.

In Canada, by contrast, the 1982 Constitution Act recognizes three politically distinct groups of Aboriginal peoples: Indians (First Nations), Inuit, and Métis. In the British North America Act of 1867 the federal government was given responsibility for 'Indian and lands reserve Indians' and the provincial governments the responsibility for off-reserve services. The situation is complicated: First Nations people are distinguished as Status or Non-Status indigenous, with a Status Indian being accorded rights under the federal Indian Act, while a Non-Status Indian

identifies as First Nations but without formal recognition (Clark et al. 2010).

A significant ongoing debate about the potential benefit or harm to people who are indigenous flows from the application of these constitutional, legal, and policy frameworks. In some jurisdictions, such as Canada, there are issues in relation to the regulation of access to services, or funding of services. Potential benefits could flow from legislative and policy programmes that target resources or recognize title to land. Some argue this inevitably produces (or recognizes) a form of differentiated citizenship that has a potential for both benefits or harms (Mercer 2002, 2003).

Health and social data

Health and social outcomes for indigenous peoples are frequently observed as poor. Indigenous health status varies, reflecting in part broader social characteristics of the dominant society. There are, for example, apparent differences in health outcomes between indigenous populations in resource-rich and resource-poor societies. Although these outcomes and inequalities appear to be persistent, in a number of instances health outcomes have been shown to improve, and there are some circumstances and measures where inequalities do not exist. This section illustrates some of these patterns.

Indigenous health status data is fragmented and incomplete, and the quality varies according to the capacity, and willingness, of nations to develop information systems that monitor indigenous health outcomes, and technical and social factors shape the quality of data. Technical factors include the inclusion of data items on indigenous status within administrative data sets and health surveys, definitions of indigenous people, and the development of systems for collation, analysis, and communication of indigenous health information. Social factors include the willingness of institutions and people involved in collection and collation of health information to commit to strategies to ensure high-quality data. Even within a technically robust indigenous health system, data quality can be undermined when questions about indigenous status are not systematically asked, or if indigenous people feel unsafe to answer such questions. Another challenge is the extent to which data measurement reflects indigenous peoples' values and priorities. While it is not necessarily true that indigenous people do not value aspects of health measurement framed by the biomedicine of public health standards, these measures may only partly capture different indigenous understanding and conceptions of health. Some jurisdictions are devoting resources to the development of strategies to improve the quality of indigenous health-related data. Transnational processes have also been established to provide mechanisms to ideas, resources, and best practice (Australian Institute of Health and Welfare (AIHW) 2006).

American Indians and Alaska Natives constituted approximately 1.6% of the US population in 2008 (Chino and Lavery 2010). Chino and Lavery argue that a number of demographic characteristics of these populations impact on the availability and collection of data, including their small population size, geographic dispersion, and concentration within rural and often remote areas. This is further impacted by misclassification or inconsistent collection of racial data, culturally inadequate survey methods, investigator

bias, the failure of investigators to establish rapport or trust, and factors such as community perception about use of data and the mistrust of institutions.

Data issues are even more complex across Latin American and the Caribbean (with an estimated 400 indigenous groups). In some countries health problems remain undocumented due to absence of data or publication bias. Further, the 'political nature of indigeneity also determines availability of data—in many countries indigeneity... might or might not be recognised. Even if indigeneity is measured, data are not always disaggregated by ethnicity' (Montenegro and Stephens 2006, p. 1859). The authors of a regional survey of indigenous health in Latin America and the Caribbean noted a pattern of poor health and social outcomes characterized by higher infant and maternal mortality, infectious diseases such as tuberculosis and gastroenteritis in children, and environmental contamination, as well as an increasing problem with chronic diseases such as obesity, diabetes, and heart disease (Montenegro and Stephens 2006).

In international reporting on indigenous health, regional data are sometimes used as a proxy where disaggregated data are unavailable for regions (usually rural or remote) in which indigenous people form a significant proportion of the population. The indigenous people of Cambodia, for example, constitute 1% of the total population, and, in the north-east, in particular, have a distinct economy (Donato n.d.). Although explicit reference is made to indigenous peoples in the 2007 Human Development Report from Cambodia, disaggregated data for indigenous peoples are not presented. Rather, the report shows provinces in the north-east with the highest concentrations of indigenous people have the lowest reported HDI for Cambodia (Donato n.d.). In India there are about 532 scheduled tribes (indigenous peoples regarded as socially disadvantaged). In 1991, they constituted about 8% of the total population, concentrated in five states. A lack of disaggregated health data does not allow a comprehensive analysis of health status. However, childhood mortality rates for 0–5 years were 136/1000 in Bihar and 167/1000 in Madhya Pradesh. In rural India, Scheduled Tribes have the highest proportion of the poor (54%) of any social group. Of those states with the highest rate of poverty, Bihar ranks first at 66% (Food and Agriculture Organization Investment Centre 1998).

Headline indicators

In some jurisdictions it is well documented that indigenous peoples fare worse on the sentinel headline indicators compared with non-indigenous populations. Although gaps are closing or have closed in some jurisdictions, there are no known cases in which indigenous populations exceed non-indigenous outcomes on key headline indicators. In Australia for 2005–2007, life expectancy at birth was estimated at 67 years for indigenous males and 73 years for indigenous females, representing gaps of 11.5 and 9.7 years, respectively, compared with all Australians (AIHW 2011a). Differences in estimations of life expectancy are documented across jurisdictions, although headline estimates such as this require sophisticated data systems. Even then, differences in the conceptual approach to measurement, method, and the quality of indigenous data make direct comparisons of life expectancy problematic (AIHW 2011b).

In some jurisdictions change has been documented. In the Northern Territory of Australia, indigenous life expectancy at birth rose during 1967–2004 from 52 years for males and 54 years for females to 60 years for males and 68 years for females. Māori, the indigenous people of New Zealand, accounted for about 15% of the usually resident population in the 2006 census (Ministry of Health 2010). In 1951 the difference in Māori life expectancy at birth was about 16 years for women and 14 years for men compared with the non-indigenous population. By 2006 life expectancy for both Māori and non-Māori had increased and the inequality had narrowed to around 8 years for both women and men. Life expectancy projections for the Canadian Aboriginal population show an average increase of 1–2 years from those recorded in 2001. By 2017, life expectancy for the total Canadian population is projected to be 79 years for men and 83 years for women: for the Inuit, projected life expectancy in 2017 is 64 years for men and 73 years for women, while for Métis and First Nations populations it is 73–74 years for men and 78–80 years for women (Statistics Canada 2010). Trends are mixed for the HDI (a single measure that combines life expectancy, educational attainment, and income) over the period 1990–2000 for indigenous peoples in Australia, Canada, New Zealand, and the United States. For this period, HDI scores for indigenous peoples in North America and New Zealand increased at a faster rate relative to benchmark non-indigenous populations, closing the HDI gap, whereas in Australia the HDI scores of indigenous peoples decreased, resulting in a widened gap in this context (Cooke et al. 2007).

Child mortality rates provide a useful insight into patterns of indigenous health. An analysis of global indigenous health patterns highlighted persistent inequality in infant mortality for indigenous peoples compared with non-indigenous benchmark populations. Data from distinct sources over different time periods show that inequalities were greater, and infant mortality outcomes significantly worse, for indigenous peoples in poorer countries, relative to resource-rich countries (Stephens et al. 2006). In Australia, infant mortality rates for indigenous peoples have declined over recent decades; based on these trends it is estimated that the infant mortality gap will close over the next decade (National Indigenous Health Equality Council 2010). There is evidence that this gap has closed for some indigenous populations such as native Hawaiians (Anderson et al. 2006).

Improvements in indigenous health outcomes must be interpreted within the context of broader population trends. In New Zealand improvements for Māori have not matched those of the non-Māori population, resulting in an increase in the inequalities between Māori and non-Māori in many areas (Blakely et al. 2007). All-cause mortality rates for both Māori and non-Māori have decreased over time (Blakely et al. 2007) but relative differences in all-cause mortality have increased. The standardized mortality rate ratio (Māori versus European) in 1981 was 1.83 for males and 2.30 for females. In 2004 the rate ratios had increased to 2.37 and 2.74 respectively. Similarly, cardiovascular disease mortality in all ethnic groups fell between 1981 and 2004, but rates did not decline as quickly in the Māori population as the European population. As a result, between 1981 and 2004 the Māori versus European standardized mortality rate ratios increased from 1.79 to 2.99 (males) and 2.62 to 4.04 (females) (Blakely et al. 2007).

Patterns of morbidity

Indigenous morbidity patterns should be understood within country or regional contexts. Here, infectious disease and chronic disease issues, including mental health and substance use, are briefly touched upon.

The relative importance of infectious disease partly reflects regional patterns of morbidity. Globally significant infectious diseases—tuberculosis, malaria, and HIV/AIDS—impact on distinct indigenous populations but vary according to context (Montenegro and Stephens 2006; Ohenjo et al. 2006; Gracey and King 2009). The HIV/AIDS impact, for example, is shaped by factors such as poverty, homelessness, substance misuse, and access to healthcare, and high rates have been documented in communities such as American Indians and Alaskan Natives, Canadian Aboriginal peoples, and indigenous peoples of Africa and the Asia Pacific (Gracey and King 2009). However, although a major cause of death in Namibia and Botswana (with a mortality rate in Botswana of 28/1000 population in 2004), the prevalence rate for the San people in Ganzi was lower (at 21.4%) than the national average of 35.4% (Ohenjo et al. 2006). While Latin American and Caribbean countries are experiencing rapid and complex epidemiological transition, non-communicable diseases and injuries continue to have a significant impact across the region (De Maio 2011). A survey of the disease burden caused by neglected tropical diseases in Latin America and the Caribbean noted that hookworm infection, other soil-transmitted helminth infections, and Chagas disease were the most significant group of these infectious diseases in the region followed by dengue, schistosomiasis, leishmaniasis, trachoma, leprosy, and lymphatic filariasis. This group of infections is associated with extreme poverty, and in this region is noted as prevalent among selected vulnerable populations, including indigenous populations and communities of African descent (Hotez et al. 2008). In wealthier nations, indigenous peoples have been shown to be at higher risk of infectious diseases, although their impact appears to be declining in some contexts. For example, mortality rates due to infectious diseases have significantly declined over the period 1977–2004 for indigenous Australians in the Northern Territory (Thomas et al. 2006). Similarly, since the early 1900s incidences of infectious diseases have fallen among Māori and non-Māori populations. However, the incidence of rheumatic fever is high among Māori and Pacific children and young people (40–100/100,000) when compared to the non-Māori, non-Pacific population whose rate (1/100,000) is consistent with that of other ‘developed’ nations (Craig et al. 2007; Lennon 2009; Milne et al. 2012). Furthermore, despite the overall decline in infectious disease mortality, inequalities in infectious disease risk have actually increased over the past 20 years in New Zealand for Māori and Pacific peoples (Baker et al. 2012).

The health of indigenous peoples is increasingly impacted by the global epidemic of chronic non-communicable diseases manifest in physiological, biochemical, and disease syndromes, and has been documented in indigenous populations in the Americas, Australia, and across the Pacific (Montenegro and Stephens 2006; Ohenjo et al. 2006; Gracey and King 2009). In Australia, a burden of disease analysis demonstrated that non-communicable diseases (including mental health) accounted for 70% of the difference in indigenous disease burden (as measured by disability-adjusted life years) compared with the total Australian population (Vos et al.

2007, 2008). Disease management strategies have consequently focused on lifestyle interventions or strategies to reduce behavioural risks, in conjunction with broader strategies that address the social determinants of health. These patterns of change can be multifaceted. For example, in the Northern Territory, mortality rates due to ischaemic heart disease and diabetes mellitus increased between 1977 and 2001, but this increase slowed after 1990. By comparison, death rates from chronic obstructive pulmonary disease rose before 1990, but fell thereafter. There were non-significant declines in death rates from cardiovascular diseases and rheumatic heart disease. Mortality rates from renal failure rose in those aged 50 years. The ratios of mortality rates from these chronic diseases for Northern Territory indigenous people compared to the total Australian population increased throughout the period (Thomas et al. 2006).

There is also the emerging significance of cancer morbidity and mortality. In New Zealand, the incidence of melanoma was lower among Māori than non-Māori (Robson et al. 2010), and the incidence of bowel cancer among the Māori population was lower than that of non-Māori but has risen steadily since the early 1980s and is now similar to that of non-Māori (Blakely et al. 2007). Despite the similar incidence, Māori have higher rates of mortality than non-Māori (Blakely et al. 2007; Robson et al. 2010). One study examined the role of demographics, disease characteristics, patient co-morbidity, treatment, and healthcare factors on colon cancer survival and found that Māori had significantly poorer cancer survival rates than non-Māori, which was not explained by demographic or disease characteristics (Hill et al. 2010). The most important factors were healthcare access and patient co-morbidities. Trends in indigenous cancer mortality in the Northern Territory also showed a mixed pattern—the indigenous cancer mortality rate was higher than the total Australian rate for cancers of the liver, lungs, uterus, cervix, and thyroid, and, in younger people only, for cancers of the oropharynx, oesophagus, and pancreas, but mortality rates were lower for melanoma, renal cancer, and, in older people, cancers of the prostate and bowel. Significantly increased mortality was noted for a number of preventable cancers (Condon et al. 2004; Cunningham et al. 2008). In a matched cohort study of 815 indigenous patients and 810 non-indigenous patients, after adjusting for stage at diagnosis, treatment, and co-morbidities, non-indigenous patients had better survival relative to indigenous patients (Valery et al. 2006).

Indigenous peoples have been shown to be at increased risk of mental health and substance misuse issues; for example, increasing harmful consumption of alcohol has been noted over the past two decades in San settlements and has been associated with increased reports of domestic violence (Ohenjo et al. 2006). A study of mortality for the indigenous peoples of Kamatchatka in the Russian north estimated that ‘alcohol poisoning’ accounted for 26% of violent deaths from 1958 to 1993. Further, improvements in health status and mortality over this period, which resulted from social and economic development, were eliminated by increased trauma-related mortalities (Bogoyavlensky 1997). In the Australian indigenous burden of disease study, mental health disorders (including substance use) were shown to account for 6% of the difference relative to the total Australian population, with substance use disorders accounting for 50% of this amount. Intentional harm (through suicide, homicide, and violence) accounted for a further 4% of the gap (Vos et al. 2008).

Strategies for improving health

The development of domestic health strategy of indigenous peoples reflects, in part, the characteristics of the relationships between indigenous peoples and nation states, as well as the characteristics of the broader health policy and institutional landscape. Some nation states have a relatively long history of development of indigenous health policy—in other contexts there is still little evidence of indigenous health development in national policy. National policy and planning framework components potentially include:

- ◆ A strategy to ensure healthcare resources are available on an equitable basis.
- ◆ A workforce strategy to enhance indigenous participation in the health workforce and the cultural competence of the broader health workforce.
- ◆ Mechanisms for indigenous community participation in policy and programme delivery.
- ◆ Health promotion, and disease prevention programmes.
- ◆ Consideration of relationships between western and traditional health systems (Mignone et al. 2007).
- ◆ Indigenous health information, monitoring, and evaluation systems.

The United Nations programme of action for the second International Decade of the World’s Indigenous People recommends:

- ◆ Access free of discrimination to community-based and culturally appropriate healthcare services, health education, adequate nutrition, and housing.
- ◆ Systems for collection and disaggregation of data on indigenous peoples.
- ◆ Consultation to integrate indigenous healers and health concepts into policies, programmes, and projects.
- ◆ Access, especially for women, to medical treatment information, ensuring prior and informed consent.
- ◆ National monitoring systems to report abuses and neglect within health systems.
- ◆ Programmes that address priorities including HIV/AIDS, malaria, and tuberculosis; cultural practices with negative health impacts; environmental degradation; and health problems connected to forced relocation, armed conflict, migration, trafficking, and prostitution.

The key strategies of the Pan American Health Organization align with the United Nations programme (Pan American Health Organization n.d.).

Improved access to quality, effective healthcare, based on need, is a common element to indigenous health strategy, often with a focus on development of primary healthcare systems. In New Zealand, for example, access is similar among Māori and non-Māori in absolute terms, but the excess burden of disease carried by the Māori population suggests poorer access to primary care (Ministry of Health 2010). Furthermore, a higher proportion of Māori report unmet need for primary care compared to non-Māori, and Māori experience a higher rate of admission to hospital for ambulatory sensitive conditions. This suggests current

access to primary care is not meeting health needs. Increasing access has been shown to reduce ambulatory sensitive hospitalizations among Māori and other 'high-needs' groups (Tan et al. 2012).

Additionally, indigenous health strategies have a preventive or health promotion focus. Increasingly, strategies for improving indigenous health outcomes have drawn upon frameworks, theories, and empirical research emerging from the fields of social epidemiology and the social determinants of health (Anderson et al. 2007; Carson et al. 2007; Mowbray 2007). This provides a lens through which indigenous health strategy can be developed in relation to programmes to address poverty, education, housing strategies, or antiracism strategies. Although social factors play a pivotal role in the production of indigenous health outcomes and inequalities, there is debate about how these relationships are mediated. The social gradient in health has been useful in explaining the relationship between health outcomes and social position for other populations—in which health outcomes decline with declining social position—and some have argued that it can be extended to indigenous populations (Marmot 2011). However, one review of empirical research found a less universal and less consistent social economic status patterning for indigenous Australians (Shepherd et al. 2012).

Similarly, socioeconomic status and deprivation play an important role. However, such differences play a role in shaping Māori outcomes but do not fully account for ethnic inequalities in health outcomes (Blakely et al. 2007). (Contributing factors include differences in access to health programmes and services, and ethnic differences in the quality of care.) The body of evidence examining these issues for indigenous health more generally remains incomplete but is expanding.

An international symposium on the social determinants of indigenous health reached a consensus that action in this field should take into account: the diversity of indigenous peoples; the effect of colonization; human rights; self-determination; poverty and economic development; data gaps and quality; indigenous culture and worldviews; reform of institutions and services; racism; and family and community health (Mowbray 2007).

Cultural development and strategies for improving health

Issues of cultural development and racism are frequently raised in discussions on indigenous health and well-being and often within the context of addressing the impacts of colonialism (Mowbray 2007). There are a number of plausible positive associations between the promotion and protection of indigenous languages and culture and indigenous health and its social determinants such as education and employment. Strategies to strengthen culture have the potential to enhance self-worth, improve social capital and strengthen engagement with mainstream service providers. Indigenous cultures and their protection are also afforded a central place within indigenous rights discourse. There are, for example, a number of references to culture in the *United Nations Declaration on the Rights of Indigenous Peoples* (United Nations 2008). For example:

Article 5

Indigenous peoples have the right to maintain and strengthen their distinct political, legal, economic, social and cultural

institutions, while retaining their right to participate fully, if they so choose, in the political, economic, social and cultural life of the State.

Article 8

1. Indigenous peoples and individuals have the right not to be subjected to forced assimilation or destruction of their culture.

Article 11

1. Indigenous peoples have the right to practise and revitalize their cultural traditions and customs. This includes the right to maintain, protect and develop the past, present and future manifestations of their cultures, such as archaeological and historical sites, artefacts, designs, ceremonies, technologies and visual and performing arts and literature.

Indigenous cultures continue to be distinct in relation to dominant cultures so the discussion about the link with health development is important. It should be expected that health values, behaviours, and practices of indigenous peoples are in some way culturally shaped. This may also include the ongoing application of traditional knowledge to health experiences and the ongoing utilization of traditional healing practices and traditional healers, although it should be noted that indigenous peoples may use both traditional healers as well as biomedically trained health practitioners. Culture can influence the decisions of indigenous peoples about when and why they should seek health services, their acceptance of treatment, the likelihood of adherence to treatment and follow up and the likely success of prevention and health promotion strategies. However, there is cultural diversity within indigenous populations and ongoing evidence of cultural development and dynamism. Indigenous people as with people of all cultures, respond to cultural issues in ways that demonstrate agency. Individual experiences and preferences can significantly shape choice and patterns of healthcare behaviour. Culture is not in any simple way a determinant of values and behaviour.

This is an important context when it comes to addressing questions about the potential harmful impact of some aspects of culture. For example, in some contexts it has been pointed out that indigenous cultural norms in relation to violence or gender have reinforced behaviours, which have significant negative consequences on the health and well-being of indigenous communities. Culture may impact on poor food choice or risky health behaviour. Health development may require change in values and behaviours. However, we should assume that it is quite likely that there already exists a diversity of views on issues of concern. The need to change in values and behaviours is true of all cultures, not just that of indigenous peoples. Supporting indigenous people to lead change is important to ensure that such issues can be addressed in a way that is meaningful, effective and ultimately culturally enriching.

A discussion on the relationship between culture and health would be incomplete without reference to the potential harms caused by aspects of inter-cultural relationships and racism in particular. There is a growing international literature that points to the impact of the exposure of racism on health outcomes more generally (Paradies 2006) and in relation to indigenous peoples (Larson et al. 2007; Paradies et al. 2008; Priest et al. 2011). There are a number of possible pathways through which exposure to racism could impact on health outcomes, indirectly mediated through chronic stress pathways or more directly through the impact on health-seeking behaviours, health risk behaviours, or through other determinants of health such as education or work. Cultural

change within dominant cultural groups is likely to be important for longer-term indigenous health gain perhaps through the development of effective antiracism strategies.

Recognizing success

It would be difficult to identify a contemporary indigenous population in which all health inequalities with respect to the dominant colonizing population have been eradicated. It is not, however, as we have demonstrated earlier in this chapter, difficult to find examples of indigenous peoples whose health has improved or in which some inequalities have lessened. It is important to document positive change as it can provide insights into strategies that have some potential to be more generally applied. It also moderates the view that indigenous health problems are intractable.

In order to document positive change a system needs to be in place to produce disaggregated population level data over time. The jurisdictions in which this is the case are still a small minority—such as Canada, United States, Australia, and New Zealand. Even so, measurement systems are patchy and often unable to adequately account for regional differences. There is a growing interest in the complexity of the relationship between statistical data and indigenous identities and on the development of strategies to improve the quality of national data systems (Axelsson and Skold 2011). A further challenge is that health change is complex in that some gains may be masked by emergent problems. For example, in jurisdictions in which there is evidence of improved infant health outcomes and improvements in infectious disease mortality (such as Australia and New Zealand), this has been offset by the rising impact of chronic diseases such as diabetes, ischaemic heart disease, renal disease, stroke, and cancers. It is also possible that improved longevity may have given rise to the expression of other diseases such as some cancers. Finally, it should also be noted that it is possible that some health outcomes may be improving while inequalities remain static or even worsen when outcomes are improving within the dominant populations at the same or greater rates. Importantly we need to not only document changes, but we also need to be able to attribute it so that we are able to make sure that strategies are effective or change direction when they are not.

Indigenous health inequality is a challenging issue globally. However, a number of the case studies cited in this chapter demonstrate that change is possible and these problems are not insoluble. A global perspective is very useful in that it does help to bring a broader perspective to these issues and assists in the development of effective strategies for health gain. However, as has been illustrated a number of times throughout this chapter, it also points to the significant differences in context that need to be taken into account when building local strategies and capacity.

People with disabilities

Donald J. Lollar and Elena M. Andresen

Introduction to people with disabilities

Public health has traditionally identified disability alongside morbidity and mortality as negative public health outcomes. Preventing disabilities, therefore, has been a goal of public health activities. The programmes created to prevent conditions associated with disability are, indeed, a crucial aspect of public health work in the areas of birth defects (e.g. encouraging women of child-bearing age not to drink alcohol or smoke), injuries (e.g. preventing falls or automotive crashes), chronic illnesses (reducing obesity and increasing physical activity), and promoting health while ageing. This primary prevention emphasis begs the question that asks what happens to those who become disabled in spite of our best primary prevention efforts. Individuals who fall through the public health prevention net by experiencing disabling conditions have been regarded as best served by medical and rehabilitation systems and services, thus outside the purview of public health. Medical and rehabilitative services are, indeed, crucial to those living with disabilities, but in fact do not take the place of public health emphasis on health promotion and prevention for this population or for the prevention of secondary conditions.

In recent years public health practitioners have begun to re-think this traditional stance, acknowledging that people with disabilities as a population are at greater risk for additional health and health-related problems (that is, secondary conditions), and are, therefore, worthy of appropriate public health intervention. The basic premise of this chapter, however, is that people with disabilities can and should experience a health status comparable to their peers without disabling conditions. People with disabilities can live healthy lives.

Public health's basic mission is to promote the health of populations through primary prevention activities. As applied to people with disabling conditions, this would include preventing secondary conditions, that is, those conditions for which people with disabilities are at greater risk because of their primary disabling condition. Reducing or preventing secondary conditions promotes health and reduces health expenditures. In some countries, medical care and rehabilitation services are the primary societal intervention for disability. These targeted services are rarely identified with public health activities which are focused on the general population.

This chapter will describe current issues surrounding the inclusion of disability as an evolving public health concept and people with disabilities as an emerging population in public health. The three core public health functions—assessment, policy development, and assurance—will be used to amplify our understanding

of and responsibility to this portion of the population (Institute of Medicine 1988). Specific emphasis will be placed on dimensions of disability, issues of disability across the lifespan, descriptions of international disability and public health activities, and the role of environmental factors that interact with these three public health functions. This chapter is meant to redefine disability and its conceptual and scientific relationship to public health.

As a preface, however, recent history must be understood in order to provide a context for how public health and disability are evolving towards one another. Public health, while concerned with the population as whole, has become progressively more concerned about certain populations at greater risk for disease, injury, and other aetiological agents. Health disparities have become a greater emphasis for public health in the past decade. This trend has focused primarily on ethnic minorities and other excluded groups who are more susceptible to diseases or other health conditions by virtue of being poor and marginalized with less access to healthcare. Disability, however, has not been usually included as a focus of health disparity science, policy, or programmes—but should be. Simultaneously, an international civil rights movement developed among people with disabilities over the past 25 years, culminating in the adoption by the United Nations (UN) of a Convention on the Rights of Persons with Disabilities (CRPD) in 2006 (UN 2006a). While public health has evolved from a medically based orientation, the disability rights movement has focused on disability as a human rights issue. While these two models have vastly different emphases, there is growing awareness among public health professionals that people with disabilities can be viewed as a large minority population who are more vulnerable to various co-morbid conditions or secondary conditions that are more probable due to a primary disabling condition. Table 10.7.1 provides an overview of basic differences between the perspectives.

While the medical model locates the problem within the individual and their condition, the social/rights model places the problem within society, marginalizing individuals on the basis of their medical condition. Change in the medical approach focuses on the individual while the social model focuses on the need to change societal attitudes and the environment. Intervention moves from individual treatment in the medical model to social action in the social model. Policy emphasis therefore is on health and medical care in the medical model rather than human rights policy and social action. In response to these differences, the World Health Organization (WHO) invested almost 10 years of work by international experts to refine a model that would incorporate both perspectives.

Table 10.7.1 Medical and social model perspectives

Area of concern	Medical model	Social model
Locus of problem	Individual	Society
Focus of change	Individual behaviour	Societal attitudes/culture
Changes needed	Personal adjustment	Environmental changes
Intervention strategy	Individual treatment	Social action
Policy issues	Medical/healthcare	Human rights/access to care

Conceptual model and framework

The WHO's model is becoming both the conceptual and scientific framework for integrating public health and disability.

During the past 40 years, several paradigms of disability had developed with some connection to public health. These models evolved somewhat but the WHO model currently best represents disability in the context of public health and this model was approved by the World Health Assembly in 2001. The WHO's International Classification of Functioning, Disability and Health (ICF) (WHO 2001) combines the medical and social models into what is described as a biopsychosocial model of disability. Fig. 10.7.1 depicts the ICF model. The model includes both biological and social elements in its presentation.

The WHO began work to revise its previous disability classification in the early 1990s. Over the course of almost a decade, over 800 individuals, including individuals living with disabling conditions, representing more than 60 countries participated in the revision process. The resulting product emerged as a member of the WHO family of international classifications, the most notable member being the International Classification of Diseases (ICD) (WHO 1992). The ICF took a different conceptual approach, addressing components of health rather than consequences of disease—the focus of the earlier edition. In addition, a most crucial conceptual and coding component was added to ICF—environmental factors. The importance of the environment as it interacts with health and functioning is explicit in this system. Environmental elements for the ICF interact with every other component.

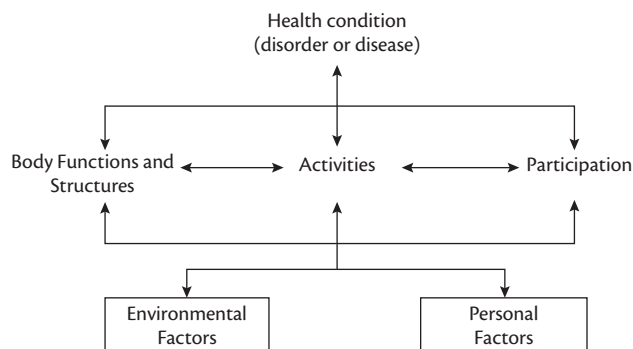

Fig. 10.7.1 International Classification of Functioning, Disability and Health Interactions among the ICF components.

Reproduced with permission from World Health Organization, *International Classification of Functioning, Disability and Health for Children and Youth*, World Health Organization, Geneva, Switzerland, Copyright © WHO 2007.

The ICF does not address causes or aetiologies, but rather addresses function and health. From the beginning, then, the emphasis was to provide a complement to the ICD. In addition, the purpose of the classification is to provide a foundation for the scientific study of function, health, and disability, as well as providing a common language to be used across populations, sectors, age groups, and users. The coding system outlined in the ICF allows public health professionals to collect data for population use, in addition to its use in clinical work to assess individual needs, plan interventions, and assess outcomes.

The components of the framework provided in Fig. 10.7.1 include functioning across all spheres—body structures and functions, personal activities, and societal participation. Body functions and structures, respectively, refer to the physiological functions of body systems and the anatomical parts of the body. A problem with body functions or structures is referred to as 'impairment'. A personal task or action undertaken by an individual is defined as an 'activity', and a difficulty in this area is called an 'activity limitation'. Likewise, functioning in society in a life situation is defined as 'participation', with a problem in this functioning called a 'participation restriction'. Finally, an 'environmental factor' includes any physical, social/attitudinal, and systemic element that affects the functioning of the individual, potentially in all components of body, person, and society (WHO 2001). Table 10.7.2 provides an outline of the one-level, two-character codes for each of the components of the ICF. The full coding system of the ICF allows coding up to six characters, allowing functional descriptions at both broad and granular levels. The functional codes can be used in both public health surveillance and in epidemiological studies. Of particular importance for epidemiological studies is the inclusion of qualifier codes that can be attached after the functional dimension. Qualifiers range from zero to four for severity, and encompass a spectrum from 'no problem' to 'complete problem'. In addition, qualifiers can be used clinically to show changes in limitation and participation due to interventions and can be used to monitor change over time (WHO 2001).

This framework provides the most coherent system for common understanding of disability concepts, definitions, and specific functional codes to be used in public health assessment, policy development, and assurance across countries, age groups, and sectors.

Assessment and measurement of disability

Public health assessment is defined as the regular, systematic collection and analysis of information on the health of a community or population. It should include data on health status, health needs of the population, and epidemiological and other studies of health problems. Assessment begins with a most basic tenet—one must define what health issue is to be assessed. Case definitions are crucial to appropriate identification of a health issue and are the basis for surveillance, epidemiology, and potential intervention strategies. Historically, definitions of disability and identification of those experiencing disability have varied greatly in public health or other sectors such as education, work, and economics. Definitions for the purpose of identification of those with disabilities usually fall into one of six categories.

Table 10.7.2 International Classification of Functioning, Disability and Health, ICF One-level Classifications

Body functions	Body structures
b1 Mental functions	s1 Structures of the nervous system
b2 Sensory functions and pain	s2 Eye, ear and related structures
b3 Voice and speech functions	s3 Structures for voice and speech
b4 Cardiovascular, haematological, immunological, and respiratory	s4 Cardiovascular, immunological, and respiratory structures
b5 Digestive, metabolic and endocrine	s5 Digestive, metabolic, and functions endocrine structures
b6 Genitourinary and reproductive functions	s6 Genitourinary and reproductive structure
b7 Neuromusculoskeletal and movement-related functions	s7 Structures related to movement
b8 Functions of the skin and related functions	s8 Skin and related structures
Activities and participation	Environmental factors
d1 Learning and applying knowledge	e1 Products and technology
d2 General tasks and demands	e2 Natural environment and human-made changes to environment
d3 Communication	e3 Support and relationships
d4 Mobility	e4 Attitudes
d5 Self-care	e5 Services, systems, and policies
d6 Domestic life	
d7 Interpersonal interactions and relationships	
d8 Major life areas	
d9 Community, social and civic life

Traditional approaches to defining disability for public health have focused on equating a particular diagnosis with having a disability. An individual with a diagnosis of cerebral palsy or autism, for example, would be assumed to have a disability. A second definitional approach has been to focus on the impairment, that is, if someone cannot hear in one ear or has intellectual or learning difficulty, s/he would be considered to have a disability. Thirdly, limitations in particular activities, such as self-care or mobility, have been defined as disabilities. Still another approach has been to identify those with life role problems such as working or going to school due to a health problem as having a disability. Yet another approach to definition is to identify those who need special programmes, such as special education or vocational rehabilitation or therapies such as physical, occupational, or speech therapy as, thereby, having a disability. Finally, another approach to identification is to ask individuals if they or others would identify themselves as having a disability (self-identification). Using one or several of these six different definitions in surveys or a census will produce different estimates of prevalence. For example, countries trying to assess disability using a question, such as ‘Is anyone in the household deaf, blind, or mute?’ will find a prevalence of disability in the 1–2 per cent range. On the other hand an activity-oriented question or set of questions, asking, for example, ‘Does anyone in your household have difficulty seeing a friend across the street?’ or ‘Does anyone in your household have difficulty taking care of themselves in eating, drinking, toileting, or dressing?’, the

prevalence of disability reaches double digits, and in some countries might approach 20 per cent (UN 1990).

In more developed countries, several of the six approaches to defining disability can be used according to the government agency, survey, or purpose for the definition. For example, definitions to address civil rights issues for people with disabilities will be intended to be broad to ensure rights for all identified in the population, while an agency providing compensation related to work injuries will define disability eligibility more stringently (Lollar and Crews 2003). Crews et al. (2012) compared the approaches to measuring vision loss in 12 federally funded surveys in the United States using nearly 100 vision measures. The varied questions created widely divergent prevalence estimates for vision loss, due to different questions addressing impairment, activity limitations, and/or societal participation. Authors concluded that decisions at the beginning of survey planning regarding the specific functional outcome one is wishing to measure would allow for more comparability among disability measures. At a minimum, describing the ICF dimension being measured will allow researchers to understand, if not explain, differences in prevalence figures.

Table 10.7.3 provides prevalence of disability in selected countries by source, across low-, middle-, and high-income countries. These figures highlight the different rates outlined by the various definitions described. In addition, this table highlights the trend towards higher rates of disability being found in surveys than in censuses. Censuses, however, need to be used for comparisons

Table 10.7.3 Prevalence of disability in selected countries by source^a

Censuses			Surveys		
Country	Year	% with disability	Country	Year	% with disability
United States	2000	19.3	New Zealand	2001	25.6
Canada	2001	18.5	Australia	2003	20.0
Brazil	2000	14.9	Uruguay	2004	7.6
United Kingdom	2001	17.6	Spain	2008	8.5
Poland	2002	14.3	Austria	2002	12.8
Ethiopia	1984	3.8	Zambia	2006	11.0
Uganda	2002	3.5	Sweden	2002	19.9
Mali	1987	2.7	Ecuador	2005	12.1
Mexico	2000	1.8	Netherlands	2002	25.6
Botswana	2001	3.5	Nicaragua	2003	10.3
Chile	2002	2.2	Germany	2007	8.4
India	2001	2.1	China	2006	6.4
Columbia	2005	6.4	Italy	2002	6.6
Bangladesh	2005	2.5	Egypt	2006	1.2
Kenya	1989	0.7			

^a Rates vary according to type of disability identifier questions used, and are explained in the text.

because poorer countries often have no other mechanism for data collection (Mont 2007a). Approaches that more accurately describe the population's disability prevalence are important in all countries, not just those with fewer resources.

The United Nations Statistics Division (UNSD) published the first compendium of disability statistics in 1990 (UN 1990) that included data from 55 countries, and provided prevalence estimates and differing case definitions. A major goal of the volume was to begin to set international standards for disability statistics. Since that initial effort, the UNSD has published the Guidelines and Principles for the Development of Disability Statistics (UN 2001). This document was much clearer about how national statistical offices could improve the questions used, collection methods employed, and overall approach to dissemination of data. The UN guidelines used the ICF framework to assist countries as they work towards harmonization and comparability in disability data.

In 2001, the UNSD convened a group of disability experts from around the world to address the need for disability measures to be more standardized. From this conference emerged the Washington City Group on Disability Measurement (city groups are a mechanism used by the UN to focus on specific topics and are named after the city in which they meet first.) This international group developed a short set of questions that continue to be field-tested internationally (UNSD 2012). After intensive discussion and analysis of questions used in numerous countries, a set of six questions focusing on personal activities is being tested. The questions currently cover difficulty seeing, hearing, walking, or climbing stairs, remembering or concentrating, washing oneself, and communicating (Centers for Disease Control and Prevention

(CDC) 2006a). Zambia, for example, in the 2000 Census asked 'Are you disabled in any way?' asking for a yes/no response. This was followed by a list of 'disabilities', including blind, deaf/dumb, mentally ill, mentally retarded or physically handicapped, also asking for a yes/no response. This approach produced a disability prevalence of 2.7 per cent. Using the Washington Group's six-question approach, prevalence was measured at 8.5 per cent (Madans 2012).

In nations with very limited resources, collecting systematic and ongoing data on disability may be virtually impossible. However, exceptional efforts are sometimes possible, for example, the 2005 National Disability Survey in Afghanistan (Handicap International 2006). This project developed surveys measuring the frequency of disability and characteristics of the population, for example, inclusion in education. For many poorer nations, however, data are developed with few direct internal efforts, and with the need to apply some estimating procedures.

The conclusion has been that in surveys and censuses respondents can more reliably and validly report person-level activities than diagnoses or impairments. Therefore, across settings and countries, comparable data on disabilities can be generated. There is continuing discussion about how to ensure inclusion of those with intellectual or mental health problems in sets of disability questions.

As definitions are clarified, there are then several kinds of questions that can be asked by public health about a subpopulation, such as: 'What characterizes this group, beyond its disability status?', 'What conditions are most associated with disability?', and 'Are there disparities between this group and the general

population on specific health measures such as obesity, physical activity, or smoking?’

In a recent publication from the United States, selected chronic health conditions contributing to a limitation of activity (‘disability’) indicated that arthritis and other musculoskeletal conditions were most frequently associated with limitations among working age adults, aged 18–44 years. Mental illness was the second condition most associated with activity limitations. After those two came fractures or joint injuries. With increasing age, 45–64 years, arthritis was still the most frequently cited condition associated with activity limitation, but was followed by heart and circulatory conditions. Mental illness and diabetes were also mentioned often. The same conditions were associated with activity limitations in people aged 65–74, but in the 75 years and over age group, cognitive impairment and vision or hearing problems were substantially increased. Throughout, however, arthritis and heart problems were most related to causing activity limitations (CDC 2006b).

In Australia, data have indicated that 20 per cent of people are living with a disability, also defined as limitation of activity, but also including impairments, and participation restrictions. Among the population, 6.3 per cent have experienced a profound or severe core activity limitation, indicating a need for help with self-care, mobility, or communication. Australia uses a four-factor approach to the kind of disability reported—physical or diverse, sensory or speech, psychiatric, and intellectual or learning. Fifteen per cent of the population have reported physical/diverse category as the disability most affecting their everyday life. Approximately 2 per cent of the population reported psychiatric and sensory/speech while the intellectual category contributed just under 1 per cent. As with the United States, older age groups experience more disabling conditions, but prevalence of severe disability is rather stable (Australian Institute of Health and Welfare 2006).

The Canadian Participation and Activity Limitation Survey from 2001 indicated that 12.4 per cent of individuals reported some degree of disability, defined as limitations in daily living due to a physical, psychological, or health condition. Among adults, the most common limitation was mobility, defined as having problems walking, climbing stairs, or moving from one room to another. Working-aged adults reported the next most common form of disability was from pain (69.5 per cent) (Statistics Canada 2002).

Data from the United Kingdom used ‘limiting long-term illness’ as the disability approach, and reported 16 per cent of the population in that category. As in Canada, the most common limitation was mobility, followed by lifting, carrying, and dexterity. Musculoskeletal problems were most commonly reported as the cause of limitations, then heart and circulatory difficulties, followed by respiratory disorders (Department of Health 1991).

All of these high-income countries have the ability to collect disability data from several sources (e.g. census and varied national surveys) and using several definitions (e.g. from reported impairments, activity limitations, and participation restrictions). Population-based interventions are better able to be tailored to a particular group when the characteristics of the population are more clearly understood. Low-income countries, on the other hand, are usually able to collect disability data only during a decennial census and, thus, have substantially less information for

the purpose of policy or programme development or assurance of services, whether rehabilitation or public health.

An example of characterizing those identified as having a disability, regardless of the definition, is the data from the United States. The public health agenda for the country has been established every 10 years since the 1980s. The current ‘Healthy People 2020’ includes ‘disability status’ as a demographic variable for many of the health objectives. One objective is to reduce the number of adults with disabilities who feel sad, depressed, or unhappy. The disparity between those with and those without disabilities in the general population at baseline was 21 per cent (28 per cent adults with disabilities versus 7 per cent of the general population). Likewise, a 9 per cent disparity was reported on life satisfaction between adults with and those without disabilities (United States Department of Health and Human Services 2010). In the United States, 31.2 per cent of people with disabilities report obesity, while those without disability reported 19.6 per cent. Physical inactivity was also twice as prevalent among people with disabilities as those without disabilities (22.4 per cent versus 11.9 per cent) (CDC 2006c).

In a report from the Special Rapporteur on Disability of the UN Commission for Social Development in 2006, results of a UN survey were presented. The survey included questions related to national monitoring of disability. Of the 73 countries responding, about 50 per cent had adopted an official definition of disability and 48 per cent had worked on collecting disability data. In terms of the range of data, 43 per cent were collecting data on the prevalence of disability, while 55 per cent include types of disabilities. Fifty-six per cent reported using data to develop policy (UN 2006b).

Using the ICF framework, and given the importance of the environment on the health and well-being of individuals with disabilities, assessment of environmental factors is also emerging. Satariano (1997) noted the importance of environment in the ageing process and indicated that public health professionals need to understand and conceptualize the role of the physical environment so as to enhance the independence and mobility of this population. Altman et al. (2003), using data from the National Health Interview Survey in the United States, concluded that people with disabilities are more likely to report environmental barriers to their participation in life. The type of functional or activity limitation appears to be related to which barriers are most reported, and respondents in this study emphasized physical barriers rather than attitudinal or policy barriers. This element of assessment is continuing to develop as shown by the emphasis being placed on extended sets of questions to assess environmental factors by the Washington City Group (Madans 2012).

Child disability measurement

Child disability prevalence around the world has been estimated for both the overall population of children under 18 with any disability (150,000,000 worldwide) as well as those with moderate or severe disabling conditions (93,000,000) (WHO and World Bank 2011). Assessing children and youth can be just as or more difficult than assessing adults. First, a child or youth is not usually asked to respond to questions, but rather a parent or other proxy. Second, if activity limitations are the approach used to assess, at early ages the inability to complete the tasks must be developmentally appropriate—that is, the child is not supposed to be able to

complete a task, such as dressing or toileting. Also, developmental stages make interpretation of limitations more problematic. Because of these differences, WHO empowered a working group of international consultants in childhood disability to revise the ICF so that unique aspects of child and youth development and function would be captured (Lollar and Simeonsson, 2005). The ICF-CY (Children and Youth) was approved by the WHO in 2006, and published in 2007 (WHO 2007b).

In a 2006 report from the Australian Institute of Health and Welfare, 8.3 per cent of Australian children were reported to have a disability. The report indicated the most prevalent disabling conditions related to intellectual or learning (4.3 per cent) and physical or diverse (4.2 per cent). Sensory or speech accounted for 3.4 per cent, while psychiatric conditions were reported for 1.2 per cent of the children and youth.

A 2003 study from the United States used the ICF as a framework and the National Health Interview Survey Disability Supplement from 1994–1995 to show limitations in activities among children and youth (Fedeyko and Lollar 2003). The prevalence was 12 per cent using this approach. Learning limitations were more than twice as prevalent as the next highest contributors—communication and social/emotional difficulties. Sensory limitation (vision and hearing) was a distant fourth in prevalence. The *Chartbook on Trends in the Health of Americans* (CDC 2006b) indicated that according to age, different health conditions undermine function more often. Pre-schoolers have a higher prevalence of speech problems, breathing difficulties related to asthma, and learning or other developmental problem. Learning problems and attention-deficit hyperactivity disorder were the major contributors to activity limitations among school-age children. Among older children, emotional and behavioural problems were additional important aetiologies. Stein and Silver (2002) compared four different definitions of chronic conditions and disabilities among children. The children and youth ranged in age from birth to 17 years. Using a common data set, the National Health Interview Survey from the United States, operational definitions identified between 13.7 to 17 per cent. Differing definitions including those using specific diagnoses associated with developmental disabilities, those using consequences of conditions, such as limitations, need for therapies or medication, and the use of compensatory equipment or assistive technology. They concluded that there was significant overlap in the characteristics and prevalence figures, even using different conceptual definitions.

Durkin et al. (1995) employed an activity limitation approach to develop a screener of ten questions for childhood disability. It has been used in several countries, included Bangladesh, Jamaica, and Pakistan with 15.6 per cent, 14.7 per cent, and 8.2 per cent, respectively, of children identified as having disabilities (Durkin et al. 1994). The method used to identify the children was different, however, in that the studies are not usually population-based. The Multiple Indicator Cluster Surveys (MICS) used the ten-question screener, called the Disability Module, in 20 countries and published a compendium of results (United Nations Children's Fund (UNICEF) 2008). The positive aspect is that children identified by the screener can be evaluated more thoroughly, if resources are available. The Washington City Group is currently developing another set of screener questions in collaboration with the Durkin effort.

In addition, UNICEF has begun a project to enhance collection of data on child disability with the convening of a panel to

develop a second-stage assessment to more clearly identify the specific limitations of children screened as more likely to experience disabling conditions (Cappa 2012). This assessment is based on the assumption that many countries will not have professional resources for completing a complete developmental evaluation, so the assessment will focus on community workers as interviewers with parents as primary respondents. This project will use the MICS currently used for broad health issues.

The US National Survey of Children with Special Health Care Needs has just been completed and uses a similar activity-oriented approach more explicitly following the ICF-CY model: it includes 13 questions and questions related to social and emotional limitations (Maternal and Child Health Bureau 2005). An analysis by Lollar et al. (2012) found that children with special health-care needs present clinically with various functional difficulties across an array of health conditions. The data demonstrate that functional difficulties contribute significantly to outcomes, such as emergency room visits, parental work patterns, and limitations in daily activities. Including functional difficulties alongside diagnostic/health conditions provides opportunities to provide richer characterization of children with disabilities for public health practice, training, policy, and research.

Ageing and disability

Disability is not an obligatory consequence of ageing, however some changes in function are typical, and life-long experiences or environmental influences, or personal characteristics of one's phenotype, contribute to increasing disability. The major reasons for disability at older ages are chronic conditions, and Chapter 10.8 provides an excellent overview of health conditions that lead to disability for adults (e.g. heart disease contributes the largest group of disability-adjusted life years (DALYs) among adults aged 60 and older). Gerontological research and clinical care have been slow to embrace the ICF as a framework to assess and study aetiology or outcomes of disability in older ages. Existing systems (e.g. based on the Nagi model) prevail, and assessment tools often use various types of activities of daily living (ADLs) and instrumental ADLs (see Chapter 10.8). However, disability can be assessed and measured using the function-based ICF.

At present, while some rehabilitation research and clinical assessment may be ICF-based (e.g. occupational therapy, where environment is a key aspect of assessment and intervention), the more promising avenue to have ICF-based measurement data comes from work that maps existing clinical and rehabilitation function measures to the ICF. Stroke assessment is one such group of patients (Moriello et al. 2008; Stucki and Cieza 2008; Quintas et al. 2012). When these measures are used, it is important to explicitly also include environmental measurements, because traditional ADL/IADL measures include items that rate disability directly involving a combined measurement of function with supports, and not function separately from elements like assistive technology or personal assistance.

The advantage of having good environmental evidence is demonstrated by examining US data. Trends on older adult disability have demonstrated decreasing disability among older adults in countries like the United States (Freedman 2006). Because the measures used to examine disability do not have environmental details, speculation about the trends includes the possibility that older adults in economically advantaged countries might have

gradually embraced technologies to compensate for decreasing function. An example might be that meal preparations are easier when an older adult uses a microwave and more processed foods (Freedman 2006).

Summary measures of health and disability

Public health statistics sometimes move beyond descriptive epidemiology, and further into evaluating the impact and costs of disability. Some nations use statistics that are particularly focused on evaluating the relative effectiveness of public health interventions, among which are the years of healthy life (YHL), quality-adjusted life years (QALYs), and DALYs. Each of these measures incorporates the premise that living with less than optimal health is discounted in some way. This assumes that general populations place higher value on better health. All of the measurement techniques incorporate disabilities along with health states. In practice, these measures provide a common metric in which to examine how the cost of various interventions may result in increased quality/health/disability-adjusted years of life. When examined directly, there is evidence that 'values' for different disability and health states may be different between general population members and people with disability or serious health conditions (e.g. Patrick et al. 1994; Hays et al. 1996; Kannisto and Sintonen 1997).

The DALYs indicator was developed with support from the World Bank (Murray and Lopez 1996), and has been used in numerous reports to assess public health priorities and to set a future public health agenda. Because DALYs incorporate the term disability, and because they are employed so frequently to set public health priorities, it is important that public health professionals understand the relationship between DALYs and the 'current' definitions of disability.

DALYs are based on a definition of disability that correlates with individual disease states. This emphasis on disease assumes that all disease states translate into similar activity limitations and participation restrictions, and assumes no influence of, equal influence of, or only random influence of environmental factors. Over several years, public health professionals, economists, and the disability community have questioned several of the core terms, methods, and implications of the use of DALYs, including using the term disability to describe the statistics. Chamie (1995) suggested that DALYs misrepresent the concept of disability, and it would be better using a term such as *morbidity-adjusted* or *illness-adjusted*, given the method used to generate the measure.

The method requires health professionals (not the general public) to assess the burden of 22 disease-related conditions using preference weighting—the person trade-off (PTO) method. Healthcare professional ratings, not population-based data, are used to characterize disability. The largely medical-model methodology used to generate DALYs, the lack of a functional definition of disability in most countries to identify people with disabilities, and the exclusion of people with disabilities in the development process makes the outcomes of this utility suspect (Grosse et al. 2009). Mont (2007b) suggested that DALYs were a poor indicator of how public health interventions affect or improve the lives of people with disabilities. He reported that the primary objective in the development of this indicator was to implement a metric that could help national policymakers in allocating resources to reduce poor health. Given the competing needs of people and the minimal resources available, governments have to make difficult

decisions regarding public health improvement. Mont concluded that 'an indicator that does not properly embody the intended goals can build in systematic bias against achieving them' (Mont 2007b). The use of DALYs to inform public health policy is questionable, and methods incorporating increased levels of participation by people with disabilities compared to people without disabilities should be developed. Mont and Loeb (2008) have developed a protocol for addressing impact of activity limitations and impairments on participation using population-based data from Zambia. This approach provides a more scientific and generalizable approach to measuring the impact of disabling conditions on people with disabilities. In addition, it allows monitoring of changes in participation across the population and for comparisons across populations.

In summary, whatever the source (e.g. survey, census, or administrative data), public health data should be both periodic and predictable in timing. Ideally, definitions and measures of disability can be applied across the age span, and have a common underlying functional framework that incorporates how people interact with their environment. Different depths of data, and level of specificity of disability definitions, can be useful; however, to fully understand disability at a population level, some common data standards are required. It is important that disability definitions be separated from health and social outcomes so that analyses can compare groups with and without disabilities. Finally, if disability data are to be accepted for the purpose of policy development, people with disabilities should be included at each point in the development, collection, and analysis of data. The disability community dictum of 'nothing about us without us' is particularly important as public health assesses, characterizes, and compares this population with the general population (Charlton 1998; Meyers and Andresen 2000).

Carers/caregivers/personal assistance services

Beyond obtaining the data to determine the prevalence of people with disabilities, public health should also address the needs of those who provide assistance or care to individuals with disabilities. In ICF terms, these supportive functions and relationships are an important part of the environmental influences that contribute to improved health and participation of people with disabilities. Most often, these supportive roles are filled by family members, but also may include paid caregivers or carers in societies where this is socially acceptable and among people with financial means. Because disability increases with age, global ageing (see Chapter 10.8) generates some of the increasing size of the caregiver population. Other factors include improved survival of infants and children who grow up with disability, improved survival of people following physical trauma, and changing health conditions, like obesity, that influence disability prevalence among adults (Field and Jette 2007).

Care provided by informal and paid caregivers commonly includes assistance with functions (e.g. mobility, communication) and personal care, but can extend to helping with roles such as work and parenting, or school, and includes interpersonal support from companionship. Carers UK suggests that approximately 3 million carers work in the United Kingdom and that 60 per cent of people will be a carer at some point in their life (ACE National Action for Carers and Employment 2007; Carers UK 2007). Australian data (Australian Institute of Health and

Welfare 2006) indicates that 202,000 persons are the primary carers of individuals under 65 years of age and live with the person for whom they care. Data from Canada indicate that parents of children with disabling conditions report substantial tension as a result of trying to coordinate work, family, and child-care duties, compromising the quality of life (Canadian Institute of Child Health 2000). Data from 2009 on family caregivers of older adults in the United States estimated there were over 42 million at any one time: accounting for those who provided care at some time during the year, the figure was over 61 million Americans (Feinberg et al. 2011). The economic value of this unpaid care in the United States was estimated to have increased from \$375 billion in 2007, to \$450 billion in 2009. Poorer health and increased stress are often seen to increase among those who have greater intensity and hours of caregiving (Talley and Crews 2007; DeFries and Andresen 2010; Kusano et al. 2011). Public health associations in high-income countries are only beginning to address this subject, and low-income countries are even less able to address this important health issue.

The Asian countries of Singapore and Japan are both models of successful ageing, and have two of the oldest populations in the world (UN Department of Economic and Social Affairs, Population Division 2007). However, in Japan the projected dementia estimates associated with this demographic are that 2.6 million people will experience dementia by 2015 (Yamamoto et al. 1997), a figure that suggests the large future need of caregivers. In both Japan and Singapore, this changing demographic and the accompanying need for supportive services is preceded by an historical change in women's roles. Women's increasing education and employment is accompanied by decreasing time that can be committed to traditionally expected roles in caregiving for parents (Yamamoto et al. 1997; Yeoh et al. 2009; Yeoh and Huang 2010). In Singapore, the role of caring for older adults has shifted to a national reliance on foreign domestic workers to perform the live-in work of personal assistance for both ageing adults and others with disability. These foreign women workers often have limited formal training in providing personal assistance (Yeoh et al. 2009; Yeoh and Huang 2010). Nations like Singapore and Japan will continue to consider how to approach caregiving and personal assistance for people with disabilities. The relative economic wealth of Western and other developed nations does not provide models for how less advantaged nations, with even more rapidly growing ageing populations, will deal with the needs of people with disability, and the underlying commitment to their independence and inclusion.

Policy development for disability

Data by themselves do not make a difference in public health or the lives of people with disabilities. Policy development addresses the need for public health policies using scientific knowledge in public decision-making. Integral to the development of a more consistent approach to public health data collection on disability is the uses made of those data. Since 1982 when the World Programme of Action was adopted by the UN General Assembly, disability policy has been a global mandate (UN 1982). The Standard Rules on the Equalization of Opportunities for Persons with Disabilities (UN 1993) were developed by the UN to operationalize the World Programme of Action, and were the basis for policy directions

globally. While the Standard Rules were not created to address health of people with disabilities or public health, they do impact the health of this portion of the public.

The Standard Rules are divided into three groups: preconditions for equal participation (rules 1–4), target areas for equal participation (rules 5–12), and implementation measures (rules 13–22). The end product of these rules is that people with disabilities have an opportunity to participate in society equal to that of people without disabilities. It is a step beyond traditional public health and moves beyond the emphasis on preventing disease, injury, and disability to embrace the higher-order outcome of participation. However, this is the move made when the WHO adopted as its mission to 'improve health and well-being around the globe'. This broader interpretation is the result of an ongoing interaction between public health professionals and the disability community.

It is noteworthy that Rules 2 and 3 concerning medical care and rehabilitation are the traditional roles acknowledged by public health. The emphasis in Rule 2 on Medical care is on early detection, assessment, and treatment of *impairment* that can 'prevent, reduce or eliminate disabling effects' (UN 1993). States are also encouraged to provide regular treatment and medication needed for people with disabilities to maintain or improve functioning. Rule 3 recommends that national rehabilitation programmes for all people with disabilities should be developed. Programmes should focus on the lived needs of the individuals with the goal of full participation and equality. Recommendations are that individuals be involved in their own rehabilitation, that services be available in the local community, and that advocacy groups be included in national programme planning.

Implementation measures are, in fact, the processes that must be in place for the preconditions and target areas to be addressed. Most of the target areas are really the specific outcome areas in which opportunities should arise, for example, in education, employment, recreation and sports, culture, and religion. Throughout the document, the term 'health' is rarely found. The notion of health promotion is also absent, and can only be found by a generous reading of early detection, assessment, and treatment of impairment or the provision of healthcare and related services to all people to reduce or prevent the 'disability effects of impairment' (UN 1993). An emerging area for public health intervention focuses specifically on promoting health and preventing secondary conditions often associated with primary disabilities, such as decubitus ulcers or skin sores among persons with spinal injuries. Physical activity and nutrition, smoking, and alcohol abuse, for example, are clear areas for public health policy and assurance in many countries. People with disabilities, however, are often not seen as a vulnerable population for public health messages. Formulation of policy addressing not only rehabilitation and medical services, but also health promotion and secondary condition prevention are important areas to be addressed among people with disabilities.

South Africa provided arguably the most complete national strategy interpreting the UN Standard Rules (Office of the Deputy President 1997). The White Paper on an Integrated National Disability Strategy includes policy guidelines for the major areas of the Standard Rules, including prevention, healthcare, and rehabilitation. Secondary prevention is included and suggests that the results might be the prevention of complications, such as contractures for those with cerebral palsy. Inclusion of secondary prevention is a critical element in health policy relative to disability.

A national database is being developed to provide an array of medical- and disability-related services, as well as to collect information on health-related needs and incidence of impairments. The policy objectives for data and research focus on the gaps between physical and/or mental conditions and their resources, including the environmental factors influencing their lives.

Since 2007, 137 countries have signed the first UN convention of the new century, a convention establishing the rights of people with disabilities, indicating their intent to ratify (UN 2007). The UN CRPD provides a roadmap to end discrimination and marginalization of people with physical or mental conditions and has as a goal to eliminate exploitation and abuse of this population. Its premise is that people with disabilities have an inherent right to life equal to that of people living without disabilities, and will receive equal protection and rights, including controlling their own financial affairs and the right to privacy. A shift in perspective is explicit in the CRPD. People with disabilities are not objects of pity or charity, but rather are citizens with rights and dignity, with the capacity to contribute to their society.

Health is addressed by the UN establishing both a right to health and ensuring the access to healthcare for persons with disabilities (UN 2007, Article 25). Article 25 addresses equal opportunity to the same quality and range of services for people with disabilities as for the general population. Services to identify disabling conditions early followed by appropriate intervention are mandated. This includes the prevention of secondary conditions for this population across the lifespan. Ethical decisions such as preventing the withholding of food or fluids or basic healthcare and services are also addressed in Article 25. Training of health professionals to provide clinical or public health services equally across the population is another tenet of Article 25 of the CRPD. Consistent with CRPD is the move by countries to include disability as part of their national health agenda. Countries have begun to formulate public health policy by setting national health goals.

Healthy People 2020 is the national public health agenda for the United States. The inclusion of a chapter in this volume focusing on improving the health and well-being of people with disabilities was a major step forward for public health policy in the United States (Box 10.7.1). As a foundation for setting these objectives, DATA2010 was used to identify specific health disparities for this population. The disparities of greatest concern included not getting needed healthcare, participating less in activities to encourage physical fitness, using tobacco more, having a higher percentage of overweight or obesity, receiving less social-emotional support, and having more emotional distress. In addition, annual dental visits are fewer for people with disability, and fewer women with disabilities have mammograms and Pap tests when appropriate (United States Department of Health and Human Services 2010).

Regional reports from selected countries in Asia and the Americas have been completed by the International Disability Rights Monitor Reports (Center for International Rehabilitation 2003, 2004, 2005). These reports include information from 33 countries and reflect policy data on disability measures, as well as health, rehabilitation, and medical issues. Completed most often by disability advocates in their home countries, these data reflect substantial difficulties in most areas of health, rehabilitation, and medicine.

The most recent international policy-focused project was mandated by the World Health Assembly of the WHO. A directive was initiated to develop a world report on disability. The *World Report on Disability* (WPD) was published in 2011 and provides the most comprehensive compendium of international disability information (WHO 2011). The WPD frames prevention of health conditions as a development issue, with the assumption that environmental factors, such as unsafe water and sanitation, poor roads, and unsafe workplaces, often contribute to the incidence of disabling conditions. A chapter is devoted to health among people with disabilities with the most important premise that people with disabilities are not, by definition, sick or ill. Rather, people with disabilities may live healthy lives. While certain conditions are associated with poor health, the common assumption of disability equalling illness undermines public health emphases to improve and maintain the health of this population. The WPD goes on to address secondary conditions, general health needs, as well as the need for specialty care.

Specific emphasis is given to ensuring that people with disabilities benefit equally from public health programmes as do the general population. This is the most important policy document thus far that addresses health and disability, alongside disability and well-being. The report continues to generate important and more detailed global studies. For example, a follow-up report in 2012 highlighted the issue of community inclusion for people living with intellectual disability drawing from contributing evidence in 95 countries and from over 40 detailed national profiles (Inclusion International 2012).

Child disability policy

As with public health assessment, policy issues are different for children with disabling conditions. The 1989 UN Convention on the Rights of the Child specifically addresses children with disabilities in Article 23 (UN 1989). It is committed to the notion that these children should enjoy a full life under conditions that allow them to live with dignity, self-determination, and participation in the life of their community. It indicates the right to special care and assistance for them and their families or caregivers. Finally, any such help should come without cost and should include education, training, healthcare, rehabilitation, and services with the goal of individual development and social integration. This convention has been signed by virtually all countries in the world, and provides the foundation for national policies addressing the needs of children with disabilities. Healthcare and rehabilitation are included in those rights.

Assessment can identify the magnitude of problem and the population to be targeted. Policies can be developed that indicate attention to those needing such. The final core function of public health, however, is most crucial to those individuals living with a disability—assurance.

Assurance and the health of people with disability

Assurance focuses on the certitude that needed services will be provided to individuals and communities so that health goals can be reached. Assurance also suggests that services must not only be present, but also maintained so that goals can be met. Implicit in these assertions is the notion that there are challenges or barriers

Box 10.7.1 Healthy People 2020: disability and health objectives**Systems and policies**

- DH-1** Include in the core of Healthy People 2020 population data systems a standardized set of questions that identify ‘disabilities’.
- DH-2** Increase the number of Tribes, States, and the District of Columbia that have public health surveillance and health programs for people with disabilities and caregivers.
- DH-3** Increase the proportion of U.S. master of public health (M.P.H.) programs that offer graduate-level disability and health.

Barriers to health care

- DH-4** Reduce the proportion of people with disabilities who report delays in receiving primary and periodic care due to specific barriers.
- DH-5** Increase the proportion of youth with special health care needs whose health care provider has discussed transition from pediatric to adult health care.
- DH-6** Increase the proportion of people with epilepsy and uncontrolled seizures who receive appropriate medical care.
- DH-7** Reduce the proportion of older adults with disabilities who use inappropriate medications.

Environment

- DH-8** Reduce the proportion of people with disabilities who report physical or program barriers to local wellness programs.
- DH-9** Reduce the proportion of people with disabilities who encounter barriers to participating in home community activities.
- DH-10** Reduce the proportion of people with disabilities who report barriers to obtaining the assistive devices, service animals, technology services, and accessible technologies that they need.
- DH-11** Increase the proportion of newly constructed and retrofitted U.S. homes and residential buildings that have visitable features.
- DH-12** Reduce the number of people with disabilities living in congregate care residencies.

Activities and participation

- DH-13** Increase the proportion of people with disabilities who participate in social, spiritual, recreational, community and civic activities to the degree that they wish.
- DH-14** Increase the proportion of children and youth with disabilities who spend at least 80 percent of their time in regular education programs.
- DH-15** Reduce unemployment among people with disabilities.
- DH-16** Increase employment among people with disabilities.
- DH-17** Increase the proportion of adults with disabilities who report sufficient social and emotional support.
- DH-18** Reduce the proportion of people with disabilities who report serious psychological distress.
- DH-19** Reduce the proportion of people with disabilities who experience nonfatal, unintentional injuries that require medical care.
- DH-20** Increase the proportion of children with disabilities, birth through age 2 years, who receive early intervention services in home or community-based settings.

Reproduced from US Department of Health and Human Services, Disability and Health, in *Healthy People 2020*, US Department of Health and Human Services, Washington, DC, USA, 2010, available from <http://www.healthypeople.gov/2020/topics-objectives/topic/disabilityandhealth/objectives>.

to the provision and use of services which must be addressed. Assurance suggests, when needed, the use of authority may be required so that services will be provided and that they will not be too costly to access (Institute of Medicine 1988).

Assurance of services includes not only the presence of services but also the access to those services. Access includes physical proximity or transport to reasonably travel to the services, physical accessibility to the services, policies and systems that allow financial access, and attitudes that encourage participation in the services. The services include clinical preventive services usually set as a baseline for everyone in any particular country, health promotion activities, and prevention of secondary conditions, in addition to basic medical care and rehabilitation.

Poverty and disability

A basic barrier to assurance of public health services and attention is poverty. Poverty not only contributes to acquiring a disability,

but the presence of a disability contributes to poverty, particularly in low-income countries. Braithwaite and Mont (2008) surveyed poverty assessments and disability for the World Bank and concluded that the poor data on disability status keeps us from accurately estimating the relationship that ‘common sense and anecdotal evidence would suggest’. Data that indirectly suggests this relationship however is available. Employment rates among people with disabilities are substantially lower for this group (in the United States, 75 per cent versus 37 per cent for individuals with and without disabilities, respectively) (United States Department of Health and Human Services 2010). In lower resource countries, we can assume the proportion of people with disabilities working is even lower.

Primary prevention programmes are extremely important in public health across the life span. However, even with intense efforts to prevent birth defects, developmental disabilities, injuries, and chronic illnesses, for the foreseeable future, children and adults will continue to live with disabling conditions.

Children and adults will be affected by poor nutrition, prenatal exposures and events, poorly controlled diseases, conflicts, and environmental factors. A Canadian report reflected that 'among those experiencing the worst income inequity are children with disabilities or children with parents who have disabilities' (CICH 2000). The relationship between poverty and disability has long been established, alongside the general relationship between health status and poverty (Fujiura and Kiyoshi 2000; Park et al. 2002; United Kingdom Public Health Association 2007). Yeo and Moore (2003) in discussing the relationship between poverty and disability and health status, concluded that people with disabilities are among the poorest of the poor and are not represented in international development organizations and activities. People with disabilities, for reasons such as stigma, few resources, or transport may be unable to access appropriate health, medical, or rehabilitation services. In many countries public health activities are difficult to implement for the population in general, precluding any focus on those with disability. However, societies are judged by the way they relate to the most vulnerable of their citizens. In 2004, the World Bank held a conference on development and disability. James D. Wolfensohn, then World Bank Group President, reported that the Millennium Development Goals set by the UN and World Bank could not be achieved without the inclusion of people with disabilities (Wolfensohn 2004). Increasing development and improving economic standards cannot be successful without all populations being included.

Public health services

Equal access to care and equal access to public health prevention is as important for people with disabilities as it is for the general public. Disparities in access to preventive healthcare are documented in some countries, although as we described above, data for monitoring disparities is not universal or consistent. Violence against women and children with disabling conditions is a prime example of the need for equal access to prevention and care. Ortoleva and Lewis (2012) reported on the international problem of violence towards women with disabilities, addressing both the commonalities with women in general who experience violence, while also highlighting the unique forms, causes, and results for this population of women. Services for women experiencing violence are seen as a public health issue, and women with disabilities must be included for screening, services, and programmes addressing this major problem. Likewise, children with disabilities are at greater risk of being victims of violence according to a systematic review of international studies (Jones et al. 2012). The analysis reported odds ratios of 3.68 for combined violence measures, 3.56 for physical violence, and 2.88 for sexual violence for children with disabilities using children without disabilities as the comparison. Any violence against children is unacceptable, but this disparity is appalling, and contrary to the UN conventions focusing on the rights of children and people with disabilities. Public health programmes and services should be a top priority for national efforts on behalf of this vulnerable population.

Primary prevention messages can be of equal importance for all segments of the population, including persons with disabilities. People with disabilities, for example, might be just as vulnerable, or more so, to heart problems than the general population. Public health messages are not generally tailored so that those living with

disabilities feel included. People with disabilities are sometimes even included in messages as potential outcomes of inappropriate behaviour, such as showing someone in a wheelchair in a message that promotes safe driving. Public health prevention messages should be developed to acknowledge that people with disabilities are potential recipients as well. Public health messages should also be tailored to reach individuals with disabilities. People who have limited mobility are at greater risk for weight gain than the general population because of reduced physical activity (United States Department of Health and Human Services 2006). It is also necessary to be aware that some in the disability community might interpret primary prevention activities related to injuries or screening for birth defects as inimical to their existence, and thus feel suspicious, if not angry, about public health prevention activities. Communication between public health professionals and the disability community is critical so that important public health education can be developed with participation from people living with disabilities, but without losing poignant public health messages.

Perhaps the most important public health message for individuals with disabilities is consistent with that for the general population. Encouraging children, youth, and adults to be responsible for their own health is a powerful message that is particularly cogent for people with disabilities. For anyone who experiences multiple medical interventions, there can develop a sense of losing control over one's body, and equating that loss of control over medical procedures with a loss of control over one's health. At both individual and population levels, self-efficacy, a belief in one's ability to have control over one's life and health, is an important mediating variable for positive health outcomes.

Beyond public health education are the clinical services that all countries, whether well or less developed, attempt to provide their citizens (US Preventive Services Task Force 1996). These services include immunization, cancer screening, and cardiovascular disease prevention for both men and women, health guidance regarding nutrition and physical activity, sexuality and pregnancy education, as needed, drug use education including alcohol, smoking, and other important health information. In more developed countries, medical care and rehabilitation are emphasized, while clinical preventive services are not. Often, rehabilitation becomes equated with medical rehabilitation and providers focus on the disabling condition and its medical complications. Primary care should be emphasized in the care of people with disability, so as to provide the immunizations, health screenings, education, and other primary care activities. Specialists might not be familiar with or sensitive to the need for these services in this population. Many individuals with disabilities, if they have specialized care, do not use primary care and, therefore, might not receive appropriate services. Jones and Kerr (1997) reported that individuals with cognitive impairments did not receive annual health screenings. Austin (2003) found that people with disabilities in the US state of Oregon using services funded through public mechanisms are at greater risk of developing smoking-related cancers, were more likely to be diagnosed at a later stage of cancer and, therefore, not receive timely screening for cancer. In addition, treatment was more often delayed among this population. A public health responsibility is to ensure that people with disabilities are not lost to the provision of clinical preventive services.

Secondary conditions prevention

The term ‘secondary conditions’ is new and evolving in the vocabulary and objectives of public health. Introduced in the early 1990s into public health in the United States, the term has come to denote those conditions that are preventable but are present because of a pre-established primary disabling condition. A secondary condition is one to which an individual is more susceptible by virtue of living with a disability. The term ‘secondary’ does not reflect level of importance but rather that it comes temporally after the primary condition (Lollar 1999). ‘Conditions’ was chosen to indicate that this secondary problem could have characteristics beyond the medical or even physical ones. Thus, depression could be a primary disabling condition, but could also be a secondary condition associated with a physical impairment. Social isolation is another common secondary condition not physical in nature, but certainly related to the presence of and vulnerability associated with a disabling condition. Of course, more common examples are physical fatigue from the exertion of moving a wheelchair or urinary tract infections associated with but not a required co-morbid diagnosis of spinal cord injury or spina bifida. To reiterate, an important characteristic of a secondary condition is that it can be prevented. Thus, medical, rehabilitative, and public health professionals are involved with activities to prevent secondary conditions at the individual and the population level. Given that Disabled Persons International has affiliates in more than 120 countries (Disabled Persons International n.d.), it is clear that people live with disabilities around the globe. To reiterate, medical care and rehabilitative services are crucial functions that might be closely associated with public health. The health of people with disabilities, however, should not be assumed to be poor by virtue of having a disabling condition. Health is also a right for people with disabilities.

Raveslout et al. (1997) completed a study of adults with disabilities across several diagnoses. The authors indicated that their results were surprising because they had assumed that each diagnostic group would report different secondary conditions. Instead, the results indicated common secondary conditions across all diagnoses. Traci et al. (2002) used a survey of common secondary conditions in a study of individuals with developmental disabilities. Physical fitness and conditioning problems were the most prevalent (59 per cent), followed by communication and mobility difficulties (57 per cent and 50 per cent, respectively). Low frustration tolerance and weight problems were next in prevalence. The authors concluded that these difficulties included major behavioural and lifestyle limitations, while more medically oriented conditions, such as bowel problems or respiratory difficulties, were reported substantially less.

This topic cannot be completed without a mention of ‘secondary benefits’. Disabling conditions usually challenge the individual and family’s functioning and participation, and often lead to secondary conditions. There are, however, benefits that may come as a result of living with a disability or being a family member. Benefits often include openness to and acceptance of differences in other human beings and seeing the humanity beyond the difference. Creative problem-solving is also often required in adapting to a world that is not often accommodating. Strength of will is also often developed by living with a disabling condition due to increased physical and emotional energy required to complete tasks (Lollar 2006). Friendships based on the shared experience of disability provide

both social and emotional support, and the identifications created are often long-lasting. These benefits may become protective factors for future adjustment and participation for both children and adults, and should be included in public health evaluation, policy, and assurance. Prevention of secondary conditions should be an integral part of any nation’s public health agenda for people with disabilities, regardless of the healthcare financing system.

Public health interventions

Interventions must be provided at both an individual and a population level. Using a self-efficacy conceptual model, several programmes have been developed to improve the health and well-being of people with disabilities. Seekins et al. (1991) have developed *Living Well with a Disability*, an eight-session workshop co-led by people with disabilities and a professional that helps participants learn to set health goals and find ways to meet them. This approach has reduced secondary conditions and medical visits among the participants. Some 15 US states among the 50 have implemented the programme. In addition, state programmes have also been instituted that educate healthcare providers about how to make their physical office space and medical staff attitudes more accessible to those with disabilities (e.g. North Carolina Office on Disability and Health 1999) and US national associations have followed suit (e.g. Chun 2011).

The WHO begins with the notion that many countries with low incomes have medical care and rehabilitation consistent with those poor resources. These services subsequently are equated with public health. This translation of medicine and rehabilitation into public health is a necessary, but not sufficient, approach to improving the health and well-being of people with disabilities. Medical care is important, even critical, for all citizens regardless of disability status. Rehabilitation services, whether medical, educational, vocational, or social, are specific services focused on outcomes related to the designated area—for example, work or school. The lived experience of individuals with disabilities is much broader than just medicine or rehabilitation, even defined broadly. Public health must encompass these services, as needed, but must also include those services discussed in previous sections—health education, preventive services, prevention of secondary conditions, and environmental facilitators of health and well-being.

Towards this end, WHO community-based rehabilitation (CBR) activities have been developed in more than 90 countries and strive to provide comprehensive strategies to include people with disabilities in the life of their communities (WHO 2007a). This emphasis, sponsored by the WHO, focuses on providing equal access to medical and rehabilitation services, but also to education, employment, participation in sport and numerous other community activities. Public health professionals, in conjunction with CBR staff, can collaborate to provide the expertise from both public health and the disability community that will improve the health of people with disabilities. The *World Report on Disability* provides a strong case for the utility of CBR throughout the world (WHO and World Bank 2011).

Major directions

Communication, cooperation, coordination

The most pressing need is for public health and disability communities to acknowledge their respective perspectives of the other.

Public health professionals do not easily acknowledge that people with disabilities are a legitimate population, and a minority, that deserves public health attention. The disability community must accept that health is a core issue for all people, and particularly for themselves, because they are often more vulnerable to additional health problems. The public health community can be a strong partner towards improving health and well-being among people with disabilities. Likewise, the disability community can assist the public health community in achieving these goals.

There is a growing interaction between public health professionals and members of the disability community. A prime example of this communication and cooperation was a leader in Disabled Persons International co-chairing the WHO Environmental Task Force to complete the ICF. On the Disabled Persons International website there is support for use of the ICF to conceptualize disability and to collect data using ICF definitions (Disabled Persons International n.d.). In the United Kingdom, a report on the 'Life Chances of Disabled People' has been completed by disability researchers and addresses inclusion of people with disabilities (Prime Minister's Strategy Unit 2005). The Office on Disability Issues has created an advisory body of 23 people with disabilities called Equality 2025, whose responsibility it is to advise government on disability issues, including health and well-being. Likewise, in 2006 the UN Department of Social and Economic Affairs commissioned an audit to evaluate the accessibility of the Internet for people with disabilities (Nomensa 2006). Five sectors from the CRPD were selected for assessment—travel, finance, media, politics, and retail. Importantly, health was not included. The evaluation concluded that only three sites among the 100 audited from 20 countries achieved appropriate accessibility ratings, and that there was a failure around the world to provide basic levels of Internet accessibility for those living with disabilities. As noted above, community inclusion of people with intellectual disability also has been evaluated (Inclusion International 2012).

In 2001 and 2002, the UN sponsored two workshops on measuring disability. The groups were composed equally of disability advocates and national statistical office representatives from the same countries. English-speaking countries in eastern Africa met in Kampala in 2001, and the ESCWAR region, including Arab-speaking countries and Israel met in Cairo, Egypt in 2002 (UN Statistics Division 2001, 2002). During each of the 2 weeks, the groups interacted to come to a better understanding of how disability statistics and disability policy were connected and the advocates and statisticians developed pilot questions to be used in censuses or surveys in their countries. Participation and involvement of service users and carers have not been the norm, but should become part of every nation's public health efforts to achieve valid disability data and pragmatic disability policy.

Currently, the joint project between the Washington City Group and UNICEF relative to disability measures for children is a prime example of coordination of effort on behalf of children with disabling conditions.

Disability framework and measurement

The WHO disability framework approved in 2001, along with the children's version approved in 2006, provide the foundation for public health functions to be achieved. The ICF is finding more traction in countries around the world. Clinical use of ICF codes is found in Germany with the work of Stucki et al. (2002a, 2002b).

Physicians throughout Italy are being trained to use ICF coding alongside ICD codes in clinical work (Disability Italian Network 2005). The Measuring Health and Disability in Europe (MHADIE) project of the European Union is implementing an ICF approach in addressing a standardized approach to data collection on disability in its 25 member states (MHADIE 2005).

Surveys have been incorporating the ICF framework in Qatar (R.J. Simeonsson, personal communication) and in the United States (Maternal and Child Health Bureau 2005). As noted earlier, the Washington Group on disability measurement includes some 75 countries in its early efforts to develop a short set of ICF-based functional questions to identify people living with some of the most prevalent activity limitations associated with disability (CDC 2006a). There is still the challenge of identifying individuals with mental health problems or with cognitive impairments, but the process has begun. Because the WHO process for revision of both the ICD and the ICF is under the auspices of the committee on Family of International Classifications (WHO-FIC), there will be growing congruence in the use of these complementary classifications in both clinical and public health settings.

Public health education and training

Public health education is expanding around the world. A study by Tanehaus et al. (2000) indicated that schools of public health in the United States were including some disability-related coursework. As an outgrowth of this study, two products were developed. Courses have been inserted into the curriculum of several schools of public health in the United States, including Georgia State University in Atlanta, Georgia, the University of Texas/Dallas, Texas, and Oregon Health & Science University in Portland, Oregon. Second, two books addressing disability and public health have been published. One volume encompasses all major public health core areas—epidemiology, health services, global health, environmental health, and ethics (Lollar and Andresen 2010). Public health experts in these fields have contributed chapters that provide a link between public health and disability in their particular specialty and provide references and case studies for each area. Using this approach, any discipline within public health could integrate disability into its courses (Allen and Garberson 2007). A second book focuses on disability as it intersects public health (Drum et al. 2009). Finally, a specific objective in the health agenda for the US (DH-3) is to increase the proportion of US master of public health programmes that offer graduate-level courses in disability and health. Efforts will be made to address this academic goal during the next 10 years (United States Department of Health and Human Services 2010).

Conclusions

People living with disabilities have traditionally not been included in public health activities. As more people with disabilities live longer because of better nutrition, medical interventions, and public health interventions such as immunizations, there will be a greater need for this population to be included in public health interventions, to be a target for specific public health messages, and to be acknowledged as a population worthy of attention when public health planning is being instituted. This 'epidemic of survival' provides an opportunity for public health to address a minority population around the world.

People with disabilities need to be encouraged to take responsibility for their health behaviours, but also to challenge the health, social, economic, and political systems that undermine progress towards health and well-being. Public health workers and people with disability can jointly address environmental barriers to health, including non-health issues, such as access to healthcare and education, societal attitudes towards those with disabling conditions, and policies and systems, for example, health and education. Training of public health professionals in disability issues is emerging, and this education of young people can lead to long-term changes in public health perceptions and practice.

Health of older people

Julie E. Byles and Meredith A. Tavenner

Introduction to health of older people

This chapter considers the phenomenon of population ageing, health needs of older people, and approaches to health and social care. Ageing reflects biological and social processes that occur across the life course, and that affect individuals at different rates. These processes are associated with ageing, but are not synonymous with chronological age. They vary between individuals and according to characteristics such as gender, geographic location, lifestyle, and socioeconomic and ethnic background.

The definition of 'old age' varies across settings, over time, and from person to person. In the past, the United Nations (UN) and other international agencies used 60 years or older (60+) to define 'the elderly', but more recently there is a growing consensus that 65+, or even older ages, should be used. However, people over 65 years of age are not one homogenous group. Indeed, people become more different from one another as they get older. Some people will continue to work well into older age, others will retire early to enjoy leisure activities or work in voluntary capacities, some will cease work to care for frail and dependent relatives or friends, and some will stop working due to their own ill health and disability. As people age, some will age well and with little disability while others will become frail and dependent. It is essential to recognize this heterogeneity in defining needs, designing and evaluating interventions, and planning for the future for this diverse segment of the population.

Older people are sometimes categorized as 'young old' aged 60–69 years, 'old old' aged 70–79 years, and 'oldest old' aged 80 years and over. Further, as more and more people reach older ages, there is increasing interest in studying the needs and characteristics of centenarians and 'super-centenarians' (110+). Alternatively, older people have been considered as being in the 'third age', a period of personal achievement following working life; or being in the 'fourth age', defined as a time of frailty and dependency. At any age there is great variance of experience, capacity, and health status between individuals. The process of ageing is universal but not uniform.

Demographics and projections

The age of the world's population is increasing both structurally and numerically. By 2050, the number of people aged 60 years or older worldwide will exceed the number of people aged 15 years or younger. Worldwide, population ageing is 'unprecedented, without parallel in the history of humanity' (UN Department of Economic and Social Affairs (DESA), Population Division, 2001).

In 2010, there were an estimated 524 million people who were aged 65 years or older worldwide, representing 8 per cent of the total population. This population proportion is projected to rise to 21 per cent in 2050. Also in 2010, the median age of the world population was estimated to be 26 years. The country with the youngest population was Yemen (median 15 years of age), and the country with the oldest population was Japan (median 41 years). By 2050, it is anticipated that the world median age will increase to 36 years, with Spain projected to reach a median age of 55 years (UN DESA, Population Division 2001).

The rapid increase in numbers of people at older ages is shown in Fig. 10.8.1.

Older populations in many low-income countries are growing more rapidly than those in more industrialized countries. Between 2007 and 2009, 81 per cent of the world's net gain of older individuals took place in low-income countries (Kinsella and He 2009). Between now and 2050, the number of older adults in high-income countries is expected to increase by 71 per cent, which is much less than the 250 per cent increase expected for low-income countries (World Health Organization (WHO) et al. 2011). The more developed a country is, the more likely it is that ageing will occur within an affluent environment, with higher levels of overall health resources and healthcare infrastructure. Ageing in lower-income countries can also occur in the context of higher rates of infectious disease, alongside the emergent burden of chronic illness.

Figs. 10.8.2 and 10.8.3 illustrate the age and sex structure of the populations of countries at different stages of development: India and Japan. Japan's population projection is for negative growth, with greater proportions of older women, and a decreasing proportion of the working-age segment. In contrast, India is moving from a very young population profile, towards an older population, although in much lower proportions than in the United States and Japan. The UN Population Division anticipates that India's oldest age group (80 years and older) will triple from 1 to 3 per cent of the overall population (Bloom 2011). It is also projected that India's 60+ population will encompass 323 million people by 2050, which is greater than the current total US population (Bloom 2011). In the United States, by 2050, the 'oldest old' (80+) will include the youngest of the post-war baby boomers, and will represent 7.4 per cent of the entire US population (Kinsella and He 2009).

Determinants of population ageing

The process of population ageing can be considered a major success story, coming largely as a result of reductions in fertility, gains in infant and child survival, and, more recently, to gains in

Fig. 10.8.1 Population at advanced ages 80–99 years, as at 1 January, 1960, 1980, 2000 and 2004 for selected countries.

Source: data from Rau, R. et al., Continued reductions in mortality at advanced ages, *Population and Development Review*, Volume 34, Issue 4, pp. 747–68, Copyright © 2008 The Population Council, Inc., with permission from John Wiley & Sons, Inc.

life expectancy at older ages. The earliest observed influence of population ageing occurred in Europe as a result of declines in fertility and childhood mortality. In the United Kingdom, reductions in infant and childhood mortality began in the nineteenth century, and accelerated in the twentieth century initially due to improved living conditions and sanitation, and then to better nutrition, immunization, antitoxins, immune sera, and antibiotics. From the middle of the twentieth century reductions in deaths from heart disease and stroke further extended adult life expectancy. Recently, there have been further mortality declines among advantaged groups (UN DESA, Population Division 2009; WHO et al. 2011). In low-income countries, successful infant and child health programmes (such as growth chart monitoring, oral rehydration for diarrhoea, breastfeeding promotion, and immunization for common infections) are probably responsible for rapid rates of mortality decline at younger ages (UN 2012).

Fertility rates have declined dramatically across the world (UN DESA, Population Division 2011). Currently, at least 50 per cent of the world's people live in a region in which fertility rates are below replacement level. In high-income countries with low mortality rates, the replacement rate is based on an average of 2.1 children per woman in the population (UN DESA, Population Division 2011). In 2012, fertility rates were 2.06 in the United States, 1.91 in the United Kingdom, and 1.39 in Japan. The country with the highest fertility rate was Niger (7.16) and the lowest was in Singapore (0.78) (Central Intelligence Agency 2012).

Declines in fertility are attributed to urbanization, industrialization, and social mobility which have all had an influence on family structures (Kinsella and He 2009). In addition, the emancipation of women, their greater chances for education, later age at marriage, and access to contraception have all played a part (Kinsella and He 2009). China's one-child policy has had a dramatic impact on fertility, and has contributed to China's rate of population ageing (Riley 2004).

As fertility rates decline, life expectancy begins to have a greater impact on population ageing. Human life expectancy has increased dramatically over the twentieth century and is still increasing. The highest life expectancy recorded in a national population rose by 3 months per year since 1840 (Oeppen and Vaupel 2002), with more recent data showing no deceleration in this rate of change (Christensen et al. 2009). Also, while early increases in life expectancy were due to reductions in infant and child mortality, more recent gains have been due to better survival in adult life, with increases in life expectancy at age 60 and at age 80 years (Rau et al. 2008).

Fig. 10.8.4 shows the dramatic change in life expectancy at age 80 for men and women in selected countries in 1960 and 2000.

A main influence on improved adult life expectancy is the reduction in smoking, combined with improvements in treatments for cardiovascular disease (Murphy and Di Cesare 2012). However, there is evidence that these trends in increasing life expectancy

may not continue, partly because many of the gains from smoking reduction have already been observed (Christensen et al. 2009), and partly because of increases in obesity (Olshansky et al. 2005).

Increases in life expectancy have also not been uniform across the world. Declines in life expectancy have been seen in sub-Saharan Africa, largely due to the impact of AIDS and due to political upheaval (Moser et al. 2005). The impact of HIV/AIDS has been felt strongly in regions such as sub-Saharan Africa, where there has been a decrease in life expectancy from 62 years in 1990–1995 to 49 years in 2005–2010 (UN Joint United Nations Programme on HIV/AIDS, 2002). Countries of Central and Eastern Europe (CEE) (such as the Czech Republic, Hungary, and Poland) demonstrated reduced life expectancies during the 1970s and 1980s; however, life expectancies in these countries improved in the 1990s (Leon 2011). This difference in change in life expectancy reflects the dramatic effects of social, economic, and political upheaval at a societal level, and has also been attributed to high-risk consumption of alcohol, smoking, and poor diet, particularly among males (Leon 2011).

In some populations, international migration has also had a role in changing age (and gender) distributions, but generally migration has had less of an impact than fertility and mortality (Lesthaeghe and Moors 2000).

Demographic and epidemiological transitions

Population ageing and changes in life expectancy are accompanied by changes in patterns of prevalent and incident diseases. Omran (1971) described epidemiological transitions as the age of pestilence and famine, the age of receding pandemics, and the age of degenerative and man-made diseases. Countries such as China are experiencing substantial changes in economic development, along with increasing urbanization, population ageing, and changes in the health profile. Non-communicable diseases,

particularly cardiovascular diseases and cancers, are currently leading causes of morbidity and mortality. Prevailing risk factors include unhealthy diet, physical inactivity, obesity, hypertension, and tobacco use (Li et al. 2012). Similar epidemiological trends have been observed in India and Latin America, and in parts of Africa (WHO 2011). On a global scale, these epidemiological changes are substantial. For example, it is estimated that nearly 15 per cent of the global burden of diabetes is accounted for by 35 million people with diabetes in India (Siegel et al. 2008).

In addition to the rise of non-communicable disease, many rapidly ageing low-income countries are also experiencing high levels of infectious diseases including childhood infections and HIV/AIDS (WHO 2011). HIV infection predominantly affects people aged 15–49 years, but also affects people aged over 50 years. In 2007, an estimated 14 per cent of adults living with HIV in sub-Saharan Africa were aged 50 years and over (Negin and Cumming 2010). HIV also has significant implications for older grandparents and their role as caretakers of children orphaned as a result of parental HIV infection (WHO 2011).

Mortality rates and life expectancy

Mortality rates tend to increase at older ages; however, in recent decades the rate of death has slowed at all ages. Also, at advanced ages (after age 70 or 80), ‘old-age mortality deceleration’ takes place. The mortality rates of a population can be summarized in a life table which can be used to calculate life expectancy of people at different ages. Life expectancy is the average number of additional years of life that a person at a given age could expect to live, providing age-specific mortality levels remain constant (UN DESA, Population Division 2009).

Table 10.8.1 shows life expectancy at birth and age 60 for males and females in different regions of the world, and for example countries within those regions. In 2009 the highest life expectancy at birth was 86 years among females in Japan, and the lowest was 44 years among males in Malawi (WHO 2012b, table 1). However, for people who achieve ‘old age’, their life expectancy is greater than life expectancy at birth. In Malawi in 2009, a male who had already lived to 60 could expect to live to 72 years.

Inequalities in life expectancy

Life expectancy varies between countries, and between different population groups within countries. Between-country differences reduced between 1950 and 1990, largely associated with improved access to safe water and sanitation, childhood immunization, improved childhood nutrition, and declining fertility (Hosseinpoor et al. 2012). However, large inequalities in life expectancy still exist. Across low-income group countries, life expectancy remains low at 57 years (WHO 2012b, table 1).

Hosseinpoor et al. (2012) assessed country-specific deviations in life expectancy from the highest attained life expectancy at that time. This measure of inequality showed a shortfall in men’s life expectancy of around 19 years during 1950–1955, falling to and around 12 years since 1975–1980. Women tended to have a greater shortfall in life expectancy than men, and shortfalls were greatest in countries with lower incomes. Women in the low-income countries had the biggest difference in life expectancy, with a current shortfall of around 26.7 years (Hosseinpoor et al. 2012).

Within-country differences in life expectancy are observed according to gender, socioeconomic disadvantage, area of residence, occupation, and cultural groups. For example, Australian Aboriginal and Torres Strait Islander people have a life expectancy approximately 10–14 years less than the overall Australian population (Australian Bureau of Statistics (ABS) 2011). In Canada, men at age 25 have a remaining life expectancy of 55.3 years if they are in the highest income quintile, compared with 48.2 years if they are in the lowest quintile. Life expectancy at age 25 is also shorter among men reporting indigenous ancestry, with remaining life expectancy at age 25 estimated at 46.9 years for Registered Indians, 48.1 years for non-Status Indians, and 48.5 years for Métis (Tjepkema and Wilkins 2011).

Life expectancy is different to maximum life span which is the longest an individual member of a species or group has survived.

While the maximum life span that humans can achieve is widely debated, it is unlikely that we have reached it yet (Vaupel 2010). We are seeing people living longer and longer, and it is expected that many children born since 2000 in countries with high life expectancies will live to at least 100 years (Christensen et al. 2009). On current evidence, it is considered that genetic factors have a modest role in determining how long individuals live, and that most of the increase in human lifespan is due to advances in medicine and public health (Vaupel 2010). Longer lifespans will have great impact on health services and social structures, requiring radical changes to how people learn, work, and care for each other across their lives.

Causes of death at older ages

Table 10.8.2 shows the most common causes of death among people aged 60 years or over. Globally, the most common causes of death for people in this age group are cardiovascular diseases, cancers, and chronic obstructive pulmonary disease. Cardiovascular causes of death include mostly ischaemic heart disease and cerebrovascular disease. Deaths from neuropsychiatric conditions are mostly due to Alzheimer’s and other dementias. The majority of accidental deaths among people aged 65 years or over are due to falls (Rubenstein 2006).

In higher-income countries over 90 per cent of deaths among people aged 60 years or over are due to non-communicable diseases (group II), whereas in low-income countries almost 20 per cent in this age group are due to communicable diseases (group I) with most of the remainder due to diseases in group II.

Morbidity and disability

Healthy life expectancy

As the WHO has argued, as well as adding years to life, it is also important to add life to years (WHO 2012a). Healthy life expectancy (or health-adjusted life expectancy (HALE)) estimates

life expectancy, but with adjustment for time spent with a disability and/or other impairment to good health, based on severity-adjusted prevalence by age and sex. Within the context of population ageing, age-associated limitations in performing everyday activities can have substantive effects on demands and costs of healthcare and services. Healthy life expectancy estimations can help answer questions raised regarding whether extra years of life are being spent in poor or good health.

Fig. 10.8.5 presents inequalities in HALE at birth across selected countries. The best HALE is seen in low-mortality countries such as Japan where healthy life expectancy is estimated to be 75 years at birth.

A study of inequalities in life expectancies and healthy life expectancy at 50 years of age for the 25 countries in the European Union found that, on average, a 50-year-old man could expect to live until 67.3 years free of activity limitation (and a woman to 68.1 years). However, there was a great variation in healthy life expectancy between countries, ranging from 9.1 years for men in Estonia to 23.6 years for men in Denmark. There was also a greater variation in healthy life expectancy than for life expectancy. Higher healthy life expectancies were associated with higher gross domestic product, lower unemployment, and with life-long learning (Jagger et al. 2008).

If healthy life expectancy increases relative to life expectancy, then people will spend a greater proportion of their life in good health and ‘compression of morbidity’ will operate (Fries et al. 1989). If people live longer due to reduction in fatal illness, but with disability due to chronic disease then there will be ‘expansion of morbidity’. A third scenario, ‘dynamic equilibrium’, could occur if the population prevalence of some chronic diseases increases with ageing, but the progression of some degenerative diseases reduces.

Compression of morbidity may be prevailing in some populations. However, data to test this hypothesis are difficult to find and hard to interpret. Very few countries are capable of making reliable assessments over time, between geographic regions or socioeconomic groups. In some settings, there is evidence that the prevalence of disability at older ages may be decreasing, but other studies find an increase in disability (Vaupel 2010). In Denmark, it has been possible to compare the health of centenarians born in 1895–1896 with that of centenarians born in 1905, showing that among women, those in the more recent cohort had slightly better health (Engberg et al. 2008).

In the United Kingdom, both life expectancy and healthy life expectancy have increased over time (Le Grand et al. 2010). Over a 20-year period, life expectancy increased more than healthy life expectancy. Males were expected to live in poor health for an extra 2.2 years, and females for an extra 1.5 years. In contrast, the US Health and Retirement Study has found that successive cohorts of people aged 51–56 are in relatively poorer health, reporting more difficulty with daily tasks, more pain, more chronic conditions, more psychiatric problems, and higher use of alcohol (Soldo et al. 2006).

A recent study which assessed disability trends in 12 Organization for Economic Cooperation and Development (OECD) countries among individuals aged 65 years and over, reported mixed results (Lafortune et al. 2007). Disability declined among elderly people in five out of the 12 countries (Denmark, Finland, the Netherlands, the United States, and Italy). At the same time three countries demonstrated increased rates of severe

disability (Belgium, Sweden, and Japan), indicating that increased longevity can still lead to increased numbers of older people in poor health and in need of long-term care.

If compression of morbidity is to occur at a population level, greater health promotion and risk reduction activities will be needed for disadvantaged groups that have high levels of health risks. Van Baal et al. (2006) have attempted to estimate HALE for cohorts with different risk factors. Men who were aged 65 years, healthy weight and non-smokers, were likely to live a further 21 years with 16.5 of these years in good health. In contrast, smokers were expected to live 15.4 years with 9.4 years in good health. Preventing smoking is likely to result not only in more years of life, but also more years in good health. Similar effects were also observed for prevention of obesity although the absolute compression of morbidity is small. It is expected that, even if preventive activities were highly successful in reducing or postponing disability, increasing numbers of people living to very old ages means that there will also be greater numbers of people with disabling conditions. At a population level, even if compression of morbidity dominates, there will be increasing needs for health and other care as populations age.

Major causes of morbidity and disability

Worldwide, ischaemic heart disease and cerebrovascular disease and cancers are the leading cause of disability and death combined among people aged 60 years and over (measured by disability-adjusted life years (DALYs)) (see Table 10.8.3).

Other major causes of DALYs include chronic obstructive lung disease, dementias, and cataract (and other vision disorders). Older people are also susceptible to respiratory infections such as pneumonia. In regions where tuberculosis is endemic, older people are particularly vulnerable.

Alzheimer's Disease International (2013) estimate that there are more than 35 million people with dementia worldwide, and that this figure will nearly double every 20 years, passing 115 million in 2050, particularly in developing countries. Women are more

likely to develop dementia than men are, due to their greater longevity. A study of dementia incidence in seven countries (Cuba, the Dominican Republic, Venezuela, Mexico, Peru, China, and India) found an incidence rate of dementia of around 20–30 cases

per 1000 person-years. Dementia rates increased with age and were higher in women, and were inversely associated with education levels (Prince et al. 2012).

Musculoskeletal conditions (such as osteoarthritis and osteoporosis) are also common among older people, and tend to contribute to disability more than death. Considering disability rates alone, musculoskeletal disease and cardiovascular disease contributed equally as the most common causes of disability among males aged 65 or over, and musculoskeletal is the single most important contributor to disability burden for women (Klijs et al. 2011).

Falls are a major cause of disability in older adults, and account for an estimated 6 per cent of all medical expenditures for persons aged over 65 in the United States (Rubenstein 2006). Around 30 per cent of older people living in the community will fall each year, and on average, people in residential aged care will experience around two falls per year. Around 5–10 per cent of falls result in serious injuries, and both the risk of falls and the risk of injury from falls increase with age and frailty.

The prevalence of diseases and morbid disorders among older people has increased over time, partly due to earlier diagnosis of diseases such as diabetes and hypertension, but also due to rise of disabling non-fatal conditions such as arthritis (Christensen et al. 2009). Older people are also likely to have more than one condition. Most older adults have a range of active health problems that interact with each other and complicate approaches to treatments. Figures vary from study to study, with prevalence of multimorbidity at age 75 ranging from 3.5 to 98.5 per cent in studies conducted in primary care, from 13.1 to 71.8 per cent in general population samples (Fortin et al. 2012). In one Australian study of men and women aged 70 years and over, the median number of conditions per person was 7.0 (Byles et al. 2005). This state (called multimorbidity or co-morbidity) is important because it is associated with many important health outcomes such as quality of life, activities of daily living, health service utilization, and mortality.

Population statistics often do not recognize the prevalence of co-morbidity among older people. For instance, deaths and DALYs are enumerated according to the underlying cause and contributing causes are often not counted. However, while the recorded cause may be quite specific, the reality is that a number of co-morbid conditions could have caused or contributed to death or disability.

Common conditions affecting older people are associated with a range of functional limitations such as cognitive impairment, mobility restrictions, and urinary incontinence. Urinary incontinence affects 10–30 per cent of older people, and women are affected twice as often as men (Chiarelli et al. 2005). Undernutrition is another problem that commonly underlies and exacerbates many conditions affecting older people, even in countries where food supplies are reliable and plentiful.

Iatrogenic disease

Iatrogenic disease is common in older people, particularly in those taking multiple medications. While medications can be beneficial in management of multiple health problems of older people, they also have the potential to cause serious adverse effects. Older people have reduced volume of distribution for drugs, and slower rates of drug metabolism and elimination, and so are vulnerable to overdose. Reduced physiological reserve renders older people more susceptible to drug toxicity. Also, multiple medications increase the risk of drug–drug interaction. Multiple medicines

also increase medication complexity which can increase risk of medication error and reduce adherence. In high-income countries, an estimated 60–90 per cent of community-dwelling people aged 65 years and over take medications. Over 50 per cent use at least one drug on a regular basis with the average number of medications used ranging from two to five (Byles et al. 2003). Adverse drug reactions have been associated with around 30 per cent of hospital admissions among older people and it is estimated that up to half these adverse reactions could be prevented (Simonson and Feinberg 2005).

Functioning, disability, and health

The International Classification of Functioning, Disability and Health (known as the ICF) recognizes that functioning and disability occur in personal, environmental, and social contexts (Üstun et al. 2003). Using this model, successful ageing includes not only absence of disease, but also capacities in terms of mobility, self-care, and social activities and participation.

Activities of daily living (ADLs) and instrumental activities of daily living (IADLs) describe functional limitations. ADLs are the basic functions of feeding, bathing, dressing, grooming, toileting, bladder control, bowel control, transfer from bed to chair, walking and stair climbing. IADLs are higher-order activities needed to function independently in modern life, including using the telephone, going shopping, cooking meals, housekeeping, doing laundry, using transport, using medications, and managing finances. Disability on ADLs and IADLs increases with age, and is greater in women than in men. Studies of prevalence of disability on ADLs have been undertaken around the world and in different population settings. A study in Malaysia found that around 25 per cent of adults aged 65 years or over reported needing help in at least one ADL item (Hairi et al. 2010). Note, however, that older adults will experience multiple transitions moving in and out of periods of disability and recovery of function (Hardy et al. 2005).

Frailty

Frailty is a term that is commonly used to describe older people who are at risk of poor outcomes due to diminished adaptive reserve. Fried et al. (2001) have developed an operational definition of frailty (frailty phenotype) that includes decreased resiliency and reserve, cycles of decline across multiple systems, negative energy balance, sarcopenia, and decreased strength and exercise tolerance. Symptoms and signs include exhaustion, weight loss, weak grip strength, slow walking pace, and low energy expenditure. Other definitions of frailty, such as the frailty index, include the accumulation of a broader range of limitations and deficits (Lacas and Rockwood 2012). Studies have shown that deficits on the frailty index accumulate exponentially with age, and at any given age, women on average have more deficits than do men. However, women tolerate functional deficits better than men do, and have a lower risk of adverse outcomes in association with scores on the frailty index (Rockwood and Mitnisky 2011).

Mental health in older age

There are a number of reasons to expect that people experience poorer mental health in late life, due partly to psychosocial stressors and loss, but also due to increasing frailty and physical illness. Psychosocial stressors can include bereavement, as well as

financial stress, loneliness, isolation, and lack of social support. There is also a theory of terminal decline whereby people with relatively stable mental health throughout life experience sudden onset of psychological morbidity towards the end of life (Gerstorf et al. 2010).

There is a strong correlation between depression and co-morbid physical conditions, and as populations age and chronic disease rates increase, mental health conditions will also rise. Consequently, it is projected that depression will be the second leading cause of global disease burden by the year 2020 (Moussavi et al. 2007).

Perceptions of ageing

Images and stereotypes

'Ageism' was defined in 1969 by US gerontologist Robert Butler as a combination of prejudicial attitudes towards ageing and older people, discriminatory practices against older people, and institutional practices and policies that perpetuate older age stereotypes (Butler 1969). A report by the American Association of Retired Persons concluded that many Americans had misconceptions about ageing and older people, including that they are senile, asexual, and miserable (Abramson and Silverstein 2006). Although some changes have occurred for the better in terms of depictions of ageing, older adults are still generally viewed less favourably than the young.

'Middle age' and 'old age' are subjective concepts based on attributes ascribed by individuals and/or society. Such concepts can influence at which age youth ceases, and the age at which men and women are considered to be 'old'. Age UK reports that 'people aged over 70 are more likely to be seen as stereotypically warm (or friendly) rather than competent' (Abrams et al. 2011). Musaiger and D'Souza (2009) found that women were viewed as 'elderly' when aged in their 40s, but men were viewed more favourably, and were only 'elderly' when aged in their 70s (Musaiger and D'Souza 2009). Across European Social Survey countries, there was a gap of 22 years between when youth was perceived to end, and old age began. The greatest differences in perceived age occurred in Norway where youthful years ended at 33.7 years; and in Greece at 51.7 years. In comparison, old age is perceived to begin at 55.1 in Turkey, and 68.2 years in Greece (Abrams et al. 2011).

Older people's own perceptions

The Growing Old in America report (Taylor et al. 2009) explored 'markers of old age'. The study reported that 'turning 85' was the most commonly endorsed marker of what it meant to be old, with the second and third markers being 'can't live independently' and 'can't drive a car' respectively. Other markers included 'has trouble walking up stairs', 'retires from work', and 'has grey hair'. The English Longitudinal Study of Ageing found that self-assessed health was strongly related to how old individuals felt, with study participants reporting better health, and also feeling younger than their actual age (Demakakos et al. 2007).

Interviews with older adults in Australia reflected acceptance of ageist stereotypes. Participants aged 65 and 89 years described oldness as 'not trying, withdrawn, isolated, irritating, self-oriented, living outside the mainstream, unattractive, uninteresting, frail, senile, silly, over the hill, narrow-minded, a burden, lonely, vulnerable, dowdy, and unproductive' (Minichiello et al. 2000). Such

internalized ageism can be dangerous in that older adults may experience worse functional health and even reduced will to live (Levy et al. 2000). Levy et al. (2002) also found that older individuals who held more positive self-perceptions of ageing (measured over 20 years earlier) lived 7.5 years longer than individuals with less positive self-perceptions of ageing. This advantage remained after accounting for age, gender, socioeconomic status, feeling lonely, and level of functional health.

Within the context of Western societies, where older age is portrayed as negative, individuals born after the Second World War (referred to as 'baby boomers') are said to be challenging old age stereotypes. Popularly portrayed images of baby boomers have them prolonging a lifestyle plateau that involves spending their children's inheritance, enjoying empty nest 'me time' and taking a 'sea change' in retirement. These descriptions fail to account for diversity in the health and social circumstances of these birth cohorts.

Productivity and social contribution

Older people do not need to take part in paid employment to be said to contribute to a community, however, with societal emphasis pointed towards the anticipated demands that the ageing population will make, significant contributions as volunteers, carers and mentors are easily overlooked. Psychologist Erik Erikson warned that later life would consist of a period of unproductive ageing that would last for many years' duration (Erikson et al. 1986). In odds with this are the ageing baby boomers who are predicted to shift the focus away from dependency to an image of active, productive ageing. But what constitutes being productive in older age?

Too often, the use of old-age dependency ratios (whereby the number of persons aged 14 or under and persons aged 65 years or over are contrasted against the number of persons aged 15–64 years) (UN DESA, Population Division 2009), can depict anyone aged 65 years or older as unproductive. Yet, 'many older people continue to make substantial social, economic, and cultural contributions' (Lloyd-Sherlock et al. 2012). In Australia, for example, almost 30 per cent of older people participate in voluntary work (ABS 2007), contributing \$2 billion to the economy (National Seniors Productive Ageing Centre 2009). Older people are more likely than younger people to be involved in religious organizations (23 per cent), arts groups (6 per cent) and health organizations (12 per cent), often bearing substantial out-of-pocket costs themselves such as transportation to and from their volunteering activities (Council on the Aged 2008). Warburton and colleagues (2007) report that volunteering is positively associated with good health and well-being in later life, can provide feelings of being productive for those no longer in paid employment, but often goes unrecognized unless it can be quantified and counted.

Childcare is pivotal to the social and economic well-being of families, and grandparents are the largest providers of informal care. Keeping within an Australian context, the contribution of grandparents' care giving labours for grandchildren to the national economy has been estimated at approximately \$74.5 billion (Women's Health Australia 2006), with almost one in five children aged 0–11 years (19 per cent) cared for by grandparents (ABS 2005). In addition to providing temporary childcare, some grandparents are also legal guardians of their grandchildren: due to a parent's drug or alcohol problem, relationship breakdown,

trauma of some kind, mental or physical illness, or death (ABS 2005). According to the US Census 2000 Supplementary Survey, between 2.3 and 2.4 million grandparents have primary responsibility for raising 4.5 grandchildren (Hayslip and Patrick 2003; US Census Bureau 2003). In Britain, more women aged over 75 years are grandmothers in 2009 than in 1998, and higher levels of child-care are provided by grandmothers than grandfathers.

Contributing to community-based organizations through active membership can benefit both older people and the places where they live. Older people can represent a powerful force for cohesion within a neighbourhood, participating in community councils, local church groups and sports organizations. According to the UK charity organization WRVS, more time is spent by older people in leadership roles (an average of 5 hours a month) than any other age group (WRVS 2011).

Community-based organizations can play a particularly important role in older men's ageing experience, enhancing well-being and social connection beyond paid work. Projects such as *Men's Sheds*, a concept originally developed in Australia, provides space, tools and equipment to men in later life, so that they can feel involved in productive activity. Age UK has piloted its own series of Men's Sheds projects, from 2010 to 2012, evaluating older men's learning as a well-being phenomenon. Later life mentoring and learning can address concerns about older men's poor social participation, particularly in rural areas (Golding et al. 2008), and for Indigenous men, men with limited education, and men from disadvantaged socioeconomic backgrounds (Misan and Sergeant 2009).

Ageing in specific populations

Age and gender

While conditions which affect people at older ages are similar among men and women (except for breast cancer and reproductive cancers), there are differences in the incidence of these conditions and the peak age of onset. For instance, men experience peak incidence of coronary artery disease earlier than women. Lung cancer is more common among men who have had higher rates of smoking, although lung cancer is now the second most common cancer among women, reflecting their increasing smoking habits. Also, while there are few differences on self-rated health, older women have higher rates of functional disability than men: reporting a higher prevalence of arthritis, asthma, depression and cognitive loss.

Women also tend to live longer than men and so are more likely to experience disease and disability associated with advanced age. In 2009, a newborn girl could expect to live to 71 years of age (global average), while a newborn boy could expect to live up to age 66 years (WHO 2012b). Differences in male life expectancy have been partially attributed to health behaviours including a high incidence of alcohol abuse and smoking, leading to high rates of accidents, violence, and cardiovascular disease (Mathers et al. 2004; Leon 2011).

Historical adherence to a male model of health meant that many findings from clinical research were generalized from men to women. For example, protocols for diagnosing and treating heart disease were based upon research with middle-aged, white, male patients. As a result, women were diagnosed later with more advanced disease and had poorer treatment outcomes (Miller 2001).

Women's longevity also means that they are more likely to experience the death of their spouse and to spend a proportion

Table 10.8.4 Older women are far more likely than older men to be widowed

Percentage of those aged 60+ who are widowed, 1985–1997

of their older age widowed (see Table 10.8.4), very often with an accompanying loss of social status and reduced economic circumstances. For women aged 60 years or over in Northern Africa, widowhood has been as high as 59 per cent (UN DESA 2001). In parts of Africa, a woman who has been widowed has no rights to owning her late husband's land, leaving her in poverty. Older women are also especially vulnerable in the event of crises such as war, natural disaster, and famine, partly because they generally control fewer economic resources than older men, and also because much of the care of children and other vulnerable people falls to older women.

Gender differences in terms of social roles and human rights will have significant effects on the experience of ageing. For example, during the life course women may be excluded from schooling, receive lower quantities of nutritious food, have no control over household decisions, and receive no health insurance from an employer.

Ageing in rural areas

The majority of the world's population lives in rural areas. As young people leave rural areas to find work, and as older people move into rural areas in retirement, the proportion of older people in rural populations increases; and rural populations can age faster than urban populations. Social infrastructure is also

changing in rural areas, with fewer local facilities. Living in rural areas has been associated with economic hardship, poorer quality housing, less access to services, and higher commodity prices (Phillipson and Scharf 2005). However, people in these areas do also report greater social cohesion and higher levels of neighbourhood safety, when compared to people in urban areas.

Ethnic minority elders

Ethnic minority groups can be particularly vulnerable as they age. Within the WHO European Region there are approximately 75 million migrants (8.4 per cent of the total population and 29 per cent of all migrants worldwide) (WHO 2010). Inequities exist in both health of these individuals, and their access to health services. With ethnic minority groups in populations rapidly increasing, health disparities between minority and non-minority older adults have become a significant concern.

In the United Kingdom, for example, data from the Black and Minority Ethnic Elders Study demonstrated that older adults from ethnic minority groups were more likely to report worse health than the white population, particularly those of African/Caribbean or South Asian ethnicity (PRIAE Policy Research Institute on Ageing and Ethnicity 2005). Many older people in these ethnic groups are first-generation immigrants and may have particular issues as they age that relate to migration stress, their reasons for having to leave their country of birth, language limitations, and separation from family members in their country of origin. Within the Netherlands, immigrant elderly are a rapidly growing segment of Dutch society, and have poorer health, potentially due to assimilation to a new living environment, and particularly difficulties in speaking the local language (Denktaş et al. 2009).

Vulnerable older people and elder abuse

The growth of an ageing population worldwide has brought with it the possibility of an increase in the incidence of older people who will experience abuse. Difficulties in identifying abuse persist due to unclear definitions and perceptions of social and cultural contexts in which abuse can occur. The International Network for the Prevention of Elder Abuse and Neglect (INPEA) says that 'Elder abuse is a single, or repeated act, or lack of appropriate action, occurring within any relationship where there is an expectation of trust which causes harm or distress to an older person' (WHO and INPEA 2002).

Elder abuse can take various forms: physical, verbal, psychological/emotional, sexual, and financial. It can also simply reflect intentional or unintentional neglect (Biggs et al. 2009; Sev'er 2009; Acierno et al. 2010). Estimates of the prevalence of elder abuse range from 2 per cent to 27 per cent (Yan and Tang 2004; Naughton et al. 2012). Older women are more likely to be abused than older men (Laumann et al. 2008; Sev'er 2009). Moreover, elder abuse can have serious consequences for the health and well-being of older people, such as depression and being admitted to an aged care home (Lachs et al. 2002), and death.

A longitudinal study conducted by Lachs et al. (1998) found that older persons who were mistreated were three times more likely to die during a 3-year period, compared with those who did not experience abuse (taking into account adjustment for co-morbidity and other factors associated with mortality). At completion of 13-years follow-up, the authors reported that only 9 per cent of those with mistreatment were alive, compared with 41 per cent without mistreatment.

Health and social care for older people

Healthcare planners are often challenged by concerns about increasing demands and rising costs of healthcare in the face of population ageing. People aged 65 years and over tend to have more admissions to hospital than younger people, and they have longer lengths of hospital stay. They also have more visits to doctors and use more medications. However, people aged 65 years and older contribute only modestly to time trends in per capita costs of healthcare compared with the rest of the population, and it has been estimated that population ageing accounts for only a 0.5 per cent annual growth rate of healthcare expenditure (Breyer et al. 2010). It has also been noted that costs of healthcare increase more with proximity to death than with age (Palangkaraya and Yong 2009). Restricting acute and tertiary level services for older people overlooks important benefits that even very old people can gain from appropriate healthcare.

Health promotion for old age

Three stages in promoting healthy old age have been described (Kalachea and Kickbusch 1997). The first is increasing capacity for health in early life and includes good maternal nutrition, and optimizing the development of vital organs such as brain, muscle, bone, and blood vessels during childhood and early adulthood to build resources that may affect later capacity (such as increasing peak bone density to protect against osteoporosis). The second stage occurs in adult life and involves strategies to reduce damage (such as avoiding smoking), to protect against damage (balanced fruit and vegetable focused diet) or to prevent loss through lack of use (such as physical activity). The third stage is in late life and involves minimizing the progression of disease and disability, protecting against increased environmental demands or stresses, and compensating for lost capacity. Examples of these approaches to health promotion include secondary prevention of stroke, rehabilitation, exercise and strength training, social support, correction of deficits in vision and hearing, and modifications to domestic and outdoor environments.

Several key health behaviours are associated with diseases that are common in older age. These associations would suggest that primary prevention approaches are likely to be effective in reducing the incidence of disease at older ages. For example, smoking is a risk factor for cardiovascular disease, stroke, respiratory disease, and many cancers, and smoking prevention is important in reducing the incidence of these conditions, even at older ages. The British Doctors' Study shows that over 7 years of life expectancy are gained by avoiding smoking after the age of 35 years (Doll et al. 2004).

Physical activity is strongly associated with lower rates of cardiovascular disease, depression, and osteoporosis in many observational studies, and some small trials have demonstrated short-term health benefits among older participants. However, older people may find it difficult to maintain high levels of exercise, and encouragement of exercise requires attention to physical environments as well as education of the individual. Neighbourhood factors such as the availability of transport, housing density, pedestrian oriented urban design, and diversity of land use can increase physical activity (Saelens et al. 2003).

Observational studies suggest a clear association between nutrition and health at older ages. For example, the Baltimore Study of Ageing found that men who consumed at least five servings of fruits and vegetables per day and who obtained 12 per cent energy or less from saturated fat had 31 per cent lower all-cause mortality ($P < 0.05$), and were 76 per cent less likely to die from CHD ($P < 0.001$) than other men in the study (Tucker et al. 2005). However, dietary intervention studies and studies of vitamin supplementation have not demonstrated significant health benefits (Davey Smith and Ebrahim 2005; Bengmark 2006).

Obesity and overweight are increasing in prevalence and are associated with increased risk of stroke, coronary artery disease, diabetes, arthritis, and some cancers (Popkin 2011). In a review of observational studies, long-term weight loss was also associated with reduced risk of developing diabetes and cardiovascular disease (Avenell et al. 2004).

Social determinants of health

Social inequity is also a major determinant of ill health at all ages (Marmot 2005). Poor circumstances have their first impact during pregnancy, when deficiencies in nutrition, maternal stress, smoking and misuse of drugs and alcohol, insufficient exercise, and inadequate prenatal care can inhibit optimal fetal development. Taking a life course approach to health promotion, poor fetal development is a risk for health in later life. The impact of disadvantage continues throughout childhood and adult life and is manifest in terms of psychosocial stress (which can have both physical and mental health impacts), poor education, poor nutrition, social exclusion, underemployment and poor job security, and work-related stress and injury. Smoking, alcohol, and drug use are higher among people in disadvantaged circumstances. Disadvantaged people also tend to live in poorer neighbourhoods with high rates of violence and crime, in overcrowded circumstances, and potentially in areas with high levels of environmental hazards. Thus while it is useful to highlight behaviours of individuals as risk factors for ill health at later ages, addressing these problems requires that the social circumstances that underpin these behaviours are also understood and improved where possible.

A number of studies have demonstrated an association between social support and improved survival, reduced disability and healthcare use, and improved quality of life (Golden et al. 2009). It is thought that these health effects are mediated through the influence of social support on health behaviour, improved access to care, and possibly through physiological pathways. A systematic review of 30 studies of social support interventions for older people identified some evidence that educational and social activity group interventions that target specific groups can alleviate social isolation and loneliness among older people (Cattan et al. 2005). However, the methods and generalizability of the reported studies varied and more work is required to develop both theoretically sound social support interventions and better methods for evaluating the outcomes of these approaches.

Prevention of specific conditions affecting older people

Cardiovascular diseases, diabetes, and dementia

Many clinical trials provide evidence in support of the effectiveness of drug therapy in primary and secondary prevention of

cardiovascular disease (O'Keefe et al. 2009). It has been estimated that the combined effects of six preventative drugs in combination (three low-dose antihypertensives, a statin to lower cholesterol, aspirin, and folic acid) could prevent up to 88 per cent of coronary heart disease and 80 per cent of stroke (Wald and Law 2003a, 2003b). This therapy has been proposed for all people over the age of 55 regardless of cardiovascular risk, but may be more beneficial among older people and people with pre-existing disease among whom the risk:benefit ratio is greater. However, there are many cost and safety issues to consider before universal multi-chemoprophylaxis becomes common practice. Furthermore, a recent review of randomized trials of folate supplementation shows that the anticipated reductions in cardiovascular disease risk have not been achieved, although there is a modest reduction in stroke risk (Durso 2006).

Treatment of diabetes in elderly patients must consider not only the importance of glucose control, but also other health risks and priorities and patient preferences. Life expectancy should also be considered. Control of other risk factors such as lipids and hypertension, as well as glucose control, is also important and may have considerable short-term advantages. For people with shorter life expectancy, long-term control of hyperglycaemia may be less important than in younger patients (Durso 2006). As for many conditions affecting older people, randomized controlled trial evidence is lacking. Observational evidence suggests that intensive control of diabetes mellitus can have favourable effects on microangiopathy (Katakura et al. 2007). Physical activity in people with impaired glucose tolerance has been associated with reduced likelihood of developing diabetes (Bethel and Califf 2007).

There have been many epidemiological studies and randomized clinical trials assessing risk factors for dementia. Most of these identified risk factors are also risk factors for cardiovascular disease and stroke. However, there is currently no evidence that modifying these risk factors, or other interventions, will reduce the onset of dementia, although they will have benefits in reducing overall vascular disease risk (Román et al. 2012), and may have a small effect on cognitive decline (Dehnel 2013).

Falls and fractures

Numerous modifiable risk factors for falls and osteoporosis have been identified. However, reduction of fall-related injury at a population level requires that preventive activities become embedded within everyday social functions and physical structures (McClure et al. 2005). A number of interventions have been shown to reduce the risk of falls, including health/environment risk factor screening/intervention programmes, muscle strengthening and balance retraining, and home hazard assessment and modification (Gillespie et al. 2012). Multifactorial falls prevention programmes have been shown to be effective in reducing falls in community-dwelling older people, and for older people with a history of falling. Important components include group or home-based exercise (including t'ai chi), individual risk assessment, home safety assessment and modification.

Vitamin D has not been shown to reduce falls among community-dwelling people, but may be important among people with lower vitamin D levels, and may prevent falls and fractures (including hip fracture) among people living in institutional care (Avenell et al. 2009). There is evidence that bisphosphonates improve bone density and reduce osteoporotic fractures (Cranney

et al. 2002). Hormone replacement therapy (HRT) may also reduce fractures; however, recent studies show increased risk of cardiovascular disease and breast cancer and so HRT is not currently recommended for fracture prevention (Writing Group for the Women's Health Initiative 2002).

Preventive activities in primary care

Immunization

Vaccination of community-dwelling older people may be a cost-effective way to prevent hospitalization for influenza or pneumonia and deaths. However, much of the evidence for vaccination in the elderly comes from observational studies and may reflect other differences between vaccinated and non-vaccinated groups (Jefferson et al. 2010).

Medication review

Some studies have shown medication review to be beneficial for older people living in the community, for example, Zermansky et al. (2002), but other studies did not find any effect of medication review on medicines use (Allard et al. 2001; Sellors et al. 2003). One large Australian randomized controlled trial demonstrated a positive effect on medication use and a reduced incidence of falls 12 months after medication review (Pit et al. 2007).

Health assessments, case finding, and screening

Reviews of evidence for prevention-based assessment programmes for older people have come to varying conclusions, but a recent review indicates that assessments have some positive effects to reduce disability burden among older adults when based on multidimensional assessment with clinical examination (Huss et al. 2008). This review also found differences between studies in content and duration of assessments and length of follow-up. The effectiveness of assessments may depend on multiple follow-ups, and benefits may be most pronounced for the 'young-old' (under 78 years) and for those with a low risk of death (Huss et al. 2008).

Many cancer screening programmes for younger people are not promoted for older people. For instance, breast cancer screening is encouraged for women aged 40–70 (US Preventive Services Task Force 2010). Evidence for ceasing screening after age 70 is not clear since few mammography screening trials enrolled women older than 69 and no trials enrolled women older than 74. The incidence of breast cancer increases with age, but the benefits of screening may be outweighed by competing morbidities among older women. Screening for cervical cancer is not recommended for women over the age of 70 years if they have had three normal Pap smears in the past 10 years (US Preventive Services Task Force 2012). The incidence of cervical cancer decreases at older ages, and so screening older women has low yield. Also, in Western countries, many women have had a hysterectomy and do not require cervical screening. Screening for colorectal cancer is recommended for adults over the age of 50 and up to the age of 80 years depending on the person's health and co-morbidities (US Preventive Services Task Force 2009). While there is limited evidence of benefit of screening for oral cancer, assessment of the mouth, teeth, and gums is helpful for older people with cognitive impairment and who may have conditions that limit chewing, swallowing and communication (National Guideline Clearinghouse 2011).

Reablement

Even among frail older people with chronic illness, it is possible to improve independence and health status through restorative approaches to care that help people re-learn or develop new skills to manage illness and participate in daily activities. These approaches not only benefit the older person and their families, but are seen as the main strategy for addressing increasing demands for aged care. Available evidence suggests that a restorative approach to home care can be cost-effective in reducing demand for ongoing services (Ryburn et al. 2009).

Systems of care

There are many strategies that enable people to successfully manage existing specific conditions and live a normal life. Quality care for chronic diseases to prevent complications and to compensate for functional impairment is essential for optimizing health and quality of life for older people. Further, since the health needs of older people are complex, their care should be multidisciplinary and include older people as partners in their own health management. New healthcare technologies such as e-health systems provide opportunity for wider involvement of health professionals, families, and individuals.

Primary care

Primary care is considered to be of great importance in reducing healthcare inequalities and in improving the quality and outcomes of healthcare among older people. However, care for older people is central to the prevailing medical model. It is essential that the needs of growing numbers of older people are reflected in healthcare provision by examining common health problems seen among older people in primary care and matching provider training to meeting these needs. There is a risk that older people will simply receive an increasing number of medications for each of their symptoms with increasing risk of an adverse reaction, and potentially diagnosable and treatable problems will be missed.

Hospital services

Older people presenting to hospital tend to be sicker, present with more urgent conditions, and have more co-morbid diseases and medications, than young people (Bridges et al. 2004). Cardiopulmonary disorders are among the most common medical reasons for presentation, and fall-related injury is the most common surgical emergency among older people presenting to emergency departments. Adverse drug-related events (unfavourable medical events related to medication use or misuse) account for around 10 per cent of emergency department visits, the most frequently implicated medications being non-steroidal anti-inflammatory drugs, antibiotics, anticoagulants, diuretics, hypoglycaemics, beta blockers, calcium channel blockers, and chemotherapeutic agents.

Older patients tend to have complex health problems and longer length of stay than younger patients. The discipline of geriatric medicine has evolved to meet these needs, and specialist geriatric units now exist within major hospitals. A systematic review shows positive effects of hospital geriatric evaluation and management units on mortality, place of discharge, and change in functional status (Ellis et al. 2011).

Disease-specific services

Specialist services for patients suffering stroke have been evaluated in randomized controlled trials and meta-analysis, and appear to reduce mortality, disability, and institutionalization by about 20 per cent at 12 months. These units have been adopted in high-income countries, but also have the potential to substantively improve stroke outcome in low- and middle-income countries. Similar models have also been applied for management of diabetes, respiratory disease, and cardiovascular disease (Gentles and Potter 2001). Specialist services for fractured neck of femur patients (orthogeriatric services) have also been examined in small randomized controlled trials with pooled effects showing a non-significant trend towards improved survival and less dependence (Langhorne et al. 2012).

Health services for people with dementia have followed a trend of moving out of institutional care and into the community (Hilton and Jolley 2012). Multidisciplinary specialist care includes integration of specialist medical approaches with psychosocial care and support for informal caregivers.

Hospital at home and day services, rehabilitation, and transitional care

‘Hospital at home’ and early discharge schemes have been promoted in efforts to reduce demand on acute hospital services. A review of 22 trials evaluating early-discharge hospital at home schemes found little evidence of benefit or costs savings. However, early discharge schemes for older patients may reduce the pressure on acute hospital beds (Shepperd et al. 2009).

There is an increasing demand for rehabilitation for older people. Traditionally this process has occurred in hospital or other institutional settings, but more recently community-based rehabilitation options have been explored. Where countries lack investment in hospital services for elderly people, community-based rehabilitation offers an alternative model that requires evaluation. Many studies have been undertaken to evaluate this approach to rehabilitation, but these studies have not been considered adequate to provide evidence of its effectiveness (Ward et al. 2008).

Long-term care

A common approach to population ageing has been to establish institutional care, despite its costs and very limited accessibility for a majority of elderly people. In Egypt, for example, the number of aged care institutions has more than doubled over the past 20 years (Boggatz and Dassen 2005).

At any one time, the majority of older people will not live in institutions, but many will require some form of long-term care during the course of their life. In high-income countries there is a trend towards care being increasingly provided in community settings. Care in the community is now the preferred and most common care arrangement and there has been a reduction in the numbers of people in institutional care, despite the ageing of the population.

Future need for long-term care will be determined by demographic trends, the relationship between age and disability, the extent to which community care permits people to stay at home, and the willingness of relatives to provide continued unpaid help. Most of these factors will result in more rather than less need for long-term institutional care. In many countries, current levels of

provision will be inadequate to meet future needs, placing increasing demands on other health services such as acute hospitals.

Informal care and social support

Within the context of an ageing population, the role of informal carer is paramount, but may be socially and politically invisible. Within the United States, the contributions of informal carers represent an important component of the US economy, with an estimated annual economic value of approximately \$350 billion, which is more than four times the total amount spent on formal (paid) care services (Gibson and Houser 2007). A report released by Carers Australia in 2010 showed that the value of informal care rose by 33 per cent, between 2005 and 2010, to exceed \$40 billion per annum (Access Economics 2010).

Many people providing care for older people will themselves be old. UK census data show that females provide more hours of informal care than males. People aged over 65 years provide more informal care than young carers and the number of hours of care provided is similar for those elders in good, fair, or poorer health (Doran et al. 2003).

While both caregivers and care recipients generally regard home-based care as preferable to institutionalization, caregiving can be physically and emotionally taxing (Schultz and Matire 2004). Lee and Porteous (2002) found that middle-aged women providing care were less likely to be in full-time employment and they had worse physical and mental health and higher levels of stress than other women. They were less likely to be within a healthy weight range, were more likely to use medications for sleeping difficulty or depression, and had lower life satisfaction scores and higher depression scores. When women gave up their caring roles, they reported fewer visits to their general practitioner and less use of medications for nerves than current caregivers. In many cases, people who took on caring were already in poor health themselves. Legg et al. (2013) analysed data from 44,465,833 individuals free from permanent sickness or disability, of whom 5,451,902 (12.3 per cent) reported providing informal care. They reported an association between provision of care and self-reported poor health, after accounting for age, sex, ethnicity, marital status, economic activity, and education. The association also increased with the amount of care provided (Legg et al. 2013).

The tradition of family support for older people is changing in many countries as a result of economic and political conditions, women’s increased participation in paid work, and where diseases such as AIDS have affected middle-aged adults leaving older people and children without support. In China, where filial piety is a traditional value, family responsibility for older people is made explicit in policy and is incorporated into the marriage contract (Zavoretti 2006). Even so, economic development, urbanization, and demographic transition are having an impact on intergenerational support. We must ensure that the important role of unpaid care is recognized as a high priority, and that the needs of informal carers are taken into account in planning and allocating resources.

Age-friendly cities

The WHO promotes the goal of age-friendly cities that support older people, by optimizing opportunities for health, participation, and security. By 2030, two-thirds of the world’s population

will live in cities, and in these cities around one in every four people will be aged 60 years or over. Environments for older people need to consider not only design and physical features, but also infrastructure, policies, and service provision. Aspects to be addressed include housing, transport, pedestrian safety, safety from violence and crime, opportunities for employment, and social involvement of older people. Many older people may not drive a motor vehicle, or may lose their ability to drive. Older people also have more difficulty with public transport and are vulnerable as pedestrians. In Manhattan, United States, for example, almost 50 per cent of pedestrian fatalities occurred among the 17 per cent of the city aged 60 and over. Older people are also particularly vulnerable to environmental changes including heat waves, which are increasingly common in urban environments (Buffel et al. 2012).

Public health implications of population ageing

As seen in this chapter, population ageing is a global phenomenon that will have a major impact on disease and disability patterns and on health service use. A coordinated and appropriate public health response is essential if this phenomenon is to translate into an opportunity for longevity and healthy ageing, rather than a threat to global health and resources. Public health is important in monitoring trends and transition in risk factors, disease and disability, encouraging effective health promotion practices, and in setting policy for equitable and efficient use of healthcare resources for this growing population. Health promotion for older age begins in early life and continues throughout life to the oldest age. Much more knowledge is needed as to how we can optimize the conditions and experiences of ageing. Recognition of the contributions made by older people themselves to their families and communities and national wealth is also of fundamental importance in meeting the challenges of an ageing population and in meeting the health needs of increasing numbers of older people.

Summary

- ◆ Ageing is universal, but not uniform.
- ◆ Population ageing is occurring at far greater rates in low- and middle-income countries than in high-income countries, and will place considerable strains on health and social care sectors.
- ◆ Increased longevity has not been experienced uniformly across socioeconomic groups or in different countries.
- ◆ Severe disability is becoming less common in successive cohorts of older people indicating that a compression of morbidity and disability is occurring.
- ◆ Health services for older people have had dramatic effects in improving survival and reducing disability associated with the inevitable increases in chronic diseases at older ages.
- ◆ Families in all countries provide a major part of the care needed by older people but do require knowledge and support of formal health and social services.
- ◆ Public health has major roles in surveillance, prevention, and development of services for older people.

Forced migrants and other displaced populations

Catherine R. Bateman Steel and Anthony B. Zwi

Introduction to forced migrants and other displaced populations

Migration and displacement have always been features of human life but the intensification of globalization, and increased ease of travel and interconnectedness, has seen the effects of displacement reaching far beyond the immediate contexts in which they occur. Forced migration is displacement that involves coercion and the implication that those involved have moved against their will. The previous few decades with the end of the cold war, rapid globalization, increasing inequality between and within nations, ongoing wars, and conflict (United Nations High Commissioner for Refugees (UNHCR) 2006), have created a landscape where forced migration affects all populations to some extent, whether as displaced or as hosts to the displaced. Health professionals will undoubtedly be confronted with the effects of forced migration and called upon to engage in responses for those affected regardless of where they practice. This chapter aims to provide a global overview of forced migration and the public health challenges facing populations forced to move from their usual homes, in order to assist the public health professional in framing their own responses. It begins by presenting a brief history of forced migration and the legal definition of 'refugee'. We describe the emergence of categories of forced migrants that do not meet the legal definition of 'refugee', describe how these groups are treated by states, and the implications for people's lives and health. The chapter then explores the social and political factors that have influenced the treatment of refugees by states. We lay out some of the major health issues that refugees face in both developing and developed countries. The wide variety of actors involved in both protecting forced migrants and providing health services is presented, along with a discussion of the contextual conditions that have an impact, often detrimental, on the health of forced migrants. As well as describing the structural factors that create and limit health outcomes, this analysis seeks to highlight the agency and voice of forced migrants, exploring the importance of understanding and projecting these, and of appreciating the rationales for how forced migrants may act in the often chaotic situations in which they find themselves. We consider how interactions with other actors, within the complex social, political, and legal context of forced migration, may lead to seemingly unhealthy choices, and at times, barriers to engaging with services. Yet, forced migrants make choices, when possible, seeking

to protect their well-being and fight for better, and healthier, outcomes.

Causes of displacement

The global context

Forced migration reached record levels in 2011 with more people becoming refugees in that year than in any year since the start of the new millennium. Humanitarian crises in countries such as Sudan, Libya, Somalia, and Côte d'Ivoire, as well as ongoing instability in Afghanistan and Iraq amongst others, contributed to a staggering 4.3 million people being newly displaced from their homes (UNHCR 2011). Whilst war, violence, and natural disaster are major contributors, and the causes most commonly associated with forced migration, it is important to consider the broader global dynamics that shape and create the forced migration situation.

Globalization, inequality, and perceptions of crisis

Forced migration cannot be fully understood without considering the global context and the shifting global forces that shape the form and patterns of migration. Globalization and its role in shaping the dynamics of forced migration need to be considered. Although globalization is a contested concept with disputed definitions, most people accept it as a global process of integration which affects sociocultural, economic, and political domains (see Chapter 1.5). The increased ease of travel, and the cultural interconnectedness that projects visions of opportunities in distant lands, provides a context which may facilitate migration amongst those with powerful forces driving them from their homes.

The economic implications of the globalized landscape are also worthy of mention in any analysis of forced migration. There is a polarized debate over the effects of globalization on human development and health. Some commentators argue, like Feachem (2001), that the forces of economic globalization may be beneficial to the poor, increasing wealth and therefore health; while others (Baum 2001; MacDonald 2007) highlight the poor health situation in many developing countries and the vast inequities present, and suggest that globalization plays a part in generating these conditions by creating an uneven playing field and weighting the economic benefits towards those that already have power and wealth. They argue that globalization cannot be separated from economic policies that serve the interests of the wealthy, reinforcing or

exacerbating inequalities, fuelling conflicts, and contributing to public health crises in developing countries. This analysis suggests that the only way to improve health is to seriously restructure the dominant international financial institutions. Taking the middle ground, Lee (2004) suggests that rigorous, ongoing analysis is required to assess the positive and negative impacts on health within the overall conceptual domain of globalization. Zwi and Alvarez-Castillo (2003) argue that globalization has often led to poor health outcomes for vast populations and that this in turn is responsible for fuelling forced migration. Regardless of our standpoint on globalization, what it is, how it impacts on health, and its influence, what is clear is that global inequities exist and are dramatic, the impact of such inequities cannot be ignored as major contributors to forced migration, whether or not associated with violence.

Castles (2004) provides an analysis that calls for careful examination of the global context when describing forced migration dynamics. He argues that the current perception of a global 'asylum crisis' should be seen more as a crisis of North-South relationships, within which 'asylum' is but one aspect. The current picture of forced migration, he argues, is a result of disparities between 'North' and 'South'. Although the North-South conceptualization does not perhaps accurately represent the divisions we see today, we can see the dynamics he describes as 'North-South' as being between the wealthy and less-wealthy nations. While disparities exist and people search for a better life, or simply for survival, forced migration will continue. The disparity is also reflected in how the effects of forced migration are absorbed globally, further deepening the crisis in North-South relations. He shows that while there has repeatedly been a perception of impending asylum crises ever since the 1800s, which largely do not fully emerge as feared, there are some new features. He cites the increase in endemic violence and human rights violations as a feature that has increased the volume of forced migration in recent times. Castles (2004) shows, however, that for the North, there is no significant economic or social crisis resulting from forced migration and contrary to popular belief, the North has not had to absorb large influxes of people. The situation is nonetheless construed by those in the North as a crisis because it highlights the 'erosion of nation-state sovereignty'. The South, however, has absorbed the vast majority of forced migrants from neighbouring countries (Allotey and Reidpath 2003). This combined with increasingly restrictive policies of wealthy countries that seek to limit refugee absorption from the South, leads to a tension in North-South relations, and opens space for people smuggling and trafficking, further threatening the sense of control over borders that the North is seeking to maintain, and therefore deepening the sense of crisis perceived by the North. Hence the burden has been left largely with the South, while in the North, incomplete pictures of fear that exclude vulnerable people have been painted and promoted (Grove and Zwi 2006). In their review of globalization, forced migration, and health, Zwi and Alvarez Castillo (2003) suggest that public health professionals have a responsibility to examine the context and whole picture, and in so doing, to break down these 'incomplete pictures of fear' and advocate for a more humane globalization that has a chance of decreasing the poor health outcomes associated with forced migration.

Immediate drivers of displacement

There is general agreement on the range of factors that contribute to displacement and forced migration. However, the importance of particular factors, and the linkages between them, varies in different contexts. Identification of specific causes has implications for both the states involved and the migrants themselves, given that the perceived cause of displacement has an impact on the international response, the level of funding support provided, and the attitudes of host populations to those seeking protection. The health consequences of forced migration will be shaped by not only the causes of displacement, but also by the perceptions of all actors regarding these causes and their relationship to them. In this respect, the terms and context within which forced migrants are described and 'presented' greatly affects the societal response and opportunities, or constraints, operating.

Forced migration has traditionally been associated with war and violence. The conception of a refugee as defined by the United Nations (UN) Convention, fleeing from persecution to a place of safety in another country, was clear-cut and well understood. As Moore and Shellman (2004) describe, the central model was one of:

Violence in = Forced migration out.

However, whilst the main causes of involuntary displacement remain armed conflict, repression, and war, other factors such as natural disasters and development projects are also important, as are the more complex set of economic, social, and political circumstances that may lead to trafficking and people smuggling.

Martin (2002) focuses attention on natural and man-made disasters and border changes leading to statelessness, as factors which lead to forced migration, alongside the well-recognized factors related to persecution, human rights violations, repression, and conflict. Environmental factors, such as rising sea levels and extreme weather conditions, are also increasingly recognized as important. Some argue that these causes may, over time, supersede conflict as a primary cause of forced migration (Myers and Kent 1995). Resource constraints, including depleted access to land and water, and conflict over precious minerals, are likely to become increasingly important, especially as the global population increases from around 6 billion people at present to nearly 9 billion by 2050.

While all these factors are important, quantifying their effects is difficult. Data are available regarding numbers of 'Convention' refugees (see 'Categories of forced migrants' section) and also, more recently, regarding internally displaced persons (IDPs). These data may give some indication of the level of displacement produced by conflicts and violence, alongside immediate natural disasters such as tsunamis and earthquakes. However, more insidious environmental and economic effects are far harder to quantify.

The increased complexity of recent times in describing and understanding factors that cause displacement raise new concerns that go beyond the simple 'violence migration' model therefore calls for new approaches. Major challenges include an increased focus on economic migrants and those who are forced to move as a result of environmental and climate changes; there is also a rise in 'mixed migration', a term which recognizes that many migrants fall somewhere on the spectrum between forced and voluntary migration and are hard to categorize as one or the other.

Particularly important is a call for a shift in policies of protection for host countries to developing policies which address the root causes within countries from which people are forced to migrate; and a growing recognition that understanding causes may allow predictions of impending displacement as well as the identification of the means to avert large-scale displacement. Some analyses continue to support the primacy of violent conflict, or threat of conflict as the major predictor of populations leaving their homes. Moore and Shellman (2004) analysed a global sample of 40 countries and using a model that incorporated a wide range of indicators (government threat, dissident threat, government-dissident interaction, ethnic or non-ethnic civil wars, war on territory, income opportunity, political freedom and the rule of law, and cultural and family ties), they found that the first three were the primary determinants of forced migration flows. These were more important than other factors such as size of economy or type of political institution. Apodaca (1998) analysed a variety of models developed to predict forced migration and concluded that human rights violations are one of the most important predictors.

Economic migration has often been portrayed in the media as freely chosen migration that should not confer a responsibility to protect on accepting states. However, analysts such as Castles (2003) argue that forced migration is linked to economic migration and that the two are 'closely related (and indeed often indistinguishable) forms of expression of global inequalities and societal crises'. These inequities have intensified since the end of the cold war. He argues that studies of the causes of forced migration have neglected the over-arching economic and social structures which should be seen in relation to 'US political and military domination, economic globalization, North-South inequality and transnationalism' (Castles 2003).

Debates regarding causes of displacement have particular salience in relation to the protection offered to forced migrants. As subsequent sections of this chapter describe, the nature and extent of protection is often determined by perceived cause. Therefore, understanding these debates is crucial as they may have effects on what and how protection, if any, is offered to forced migrant populations.

Categories of forced migrants

Definitions of forced migration have been debated for more than 50 years, dating back to the first UN Convention on Refugees in 1951. The legal framework that emerged under the Convention centred on 'refugees' as a specially defined group and is based upon the 1951 Convention and a subsequent 1967 protocol. According to these, a refugee is a person who:

owing to a well-founded fear of being persecuted for reasons of race, religion, nationality membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable to or, owing to such fear, is unwilling to avail himself of the protection of that country. (UNHCR 2009)

This definition has been modified by regional instruments in Africa and Latin America, as described in a later section. The International Association for the Study of Forced Migration (IASFM), however, defines forced migration much more widely as:

a general term that refers to the movements of refugees and internally displaced people (those displaced by conflicts) as well as people displaced by natural or environmental disasters, chemical or nuclear

disasters, famine, or development projects. (Forced Migration Online 2008)

This definition encompasses a wide range of forced migrants, and these can be distinguished into several distinct groups (Table 10.9.1).

The definitions of other forced migrant groups, and their sources, are outlined in the following subsections. They highlight the increased attention devoted to describing, as well as defining, the many forms of forced migration that exist. The discourse and narratives presented have a marked impact on how people see, and respond to, those forced to leave their usual homes and livelihoods.

Internally displaced persons

Unlike refugees, there is no legal definition of an IDP. It is generally accepted that if a person meets the definition of a refugee, but their displacement does not take them across an international border, then they are internally displaced. The Secretary General of the UN has appointed a representative to deal with IDPs and the Office of the United Nations High Commissioner for Human Rights (OHCHR) has produced a set of Guiding Principles to address the specific needs of IDPs who are described as:

persons or groups of persons who have been forced or obliged to flee or to leave their homes or places of habitual residence, in particular as a result of, or in order to avoid the effects of, armed conflict, situations of generalized violence, violations of human rights or natural or human-made disasters, and who have not crossed an internationally recognized State border. (Deng 1998)

Asylum seekers

Asylum seekers are those who are fleeing persecution and are seeking refugee status in another country. According to the UNHCR, an asylum seeker is:

Someone who has made a claim that he or she is a refugee, and is waiting for that claim to be accepted or rejected. The term contains no presumption either way—it simply describes the fact that someone has lodged the claim. Some asylum seekers will be judged to be refugees and others will not. (UNHCR 2009)

The application referred to relates to being recognized under the 1951 Convention as a refugee and therefore being entitled to the protection and support stipulated by the Convention. They may or may not arrive in a country with authorization, nevertheless, they have a legal right to claim asylum and are therefore not 'illegal'.

Trafficked persons

The 2003 Protocol to Prevent, Suppress and Punish Trafficking in Persons, especially Women and Children, describes trafficking as:

recruitment, transportation, transfer, harbouring, or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation. Exploitation shall include, at a minimum, the exploitation of the prostitution of others or other forms of sexual exploitation, forced labour or services, slavery or practices similar to slavery, servitude or the removal of organs. (UN 2003, Resolution 25)

Table 10.9.1 Categories of forced migrants

Refugee	A person who 'owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable to or, owing to such fear, is unwilling to avail himself of the protection of that country' (UNHCR 2009)
Internally displaced persons	'Persons or groups of persons who have been forced or obliged to flee or to leave their homes' (Deng 1998). Or places of habitual residence, in particular as a result of, or in order to, avoid the effects of armed conflict, situations of generalized violence, violations of human rights or natural or human-made disasters, and who have not crossed an internationally recognized State border
Asylum seeker	'Someone who has made a claim that he or she is a refugee, and is waiting for that claim to be accepted or rejected. The term contains no presumption either way—it simply describes the fact that someone has lodged the claim. Some asylum seekers will be judged to be refugees and others will not' (UNHCR 2009)
Trafficking in persons	'Recruitment, transportation, transfer, harbouring or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation' (United Nations 2003)
Smuggling in persons	'The procurement, in order to obtain, directly or indirectly, a financial or other material benefit, of illegal entry of a person into a state, party of which the person is not a national or permanent resident' (United Nations 2000) [Article 3 (a)]
Environmentally displaced person	'A person displaced owing to environmental causes, notably land loss and degradation, and natural disaster' (Deng 1998)
Development displacees	'People who are compelled to move as a result of policies and projects implemented to supposedly enhance "development"' (Forced Migration Online 2008)

Smuggled persons

Smuggling of aliens or 'illegal migrant smuggling' is defined by the UN 2000 Protocol Against Smuggling of Migrants by Land, Sea and Air, which supplemented the UN Convention Against Transnational Organized Crime, to mean:

the procurement, in order to obtain, directly or indirectly, a financial or other material benefit, of illegal entry of a person into a state, party of which the person is not a national or permanent resident. (UN 2000, Article 3(a))

Environmentally displaced persons

The Organisation for Economic Cooperation and Development's online *Glossary of Statistical Terms* describes an environmental refugee as 'a person displaced owing to environmental causes, notably land loss and degradation, and natural disaster' (United Nations 1997). However, the term was first described by El-Hinnawi (1985), a researcher from the United Nations Environment Programme (UNEP) in 1985, who defined environmental refugees as:

those people who have been forced to leave their traditional habitat, temporarily or permanently, because of a marked environmental disruption (natural and/or triggered by people) that jeopardized their existence and/or seriously affected the quality of their life.

'Environmental disruption' in this definition is taken to mean any physical, chemical, and/or biological changes in the ecosystem (or resource base) that render it, temporarily or permanently, unsuitable to support human life. The validity of the term 'environmental refugees' has been debated greatly since that time. Actors emerge from a realm of perspectives including environmentalists, economists, and refugee advocates, each with a different interpretation of the term. Some prefer to use the term 'environmental migrant' or 'environmental displacee'; different terms establish different implications for both the individuals and states involved.

Development displacees

There is no legal definition for development displacees; however, Forced Migration Online suggests they are:

people who are compelled to move as a result of policies and projects implemented to supposedly enhance 'development'. These include large-scale infrastructure projects such as dams, roads, ports, airports; urban clearance initiatives; mining and deforestation; and the introduction of conservation parks/reserves and biosphere projects. Affected people usually remain within the borders of their country. People displaced in this way are sometimes also referred to as 'oustees', 'involuntarily displaced' or 'involuntarily resettled'. (Forced Migration Online 2008)

Interestingly, large-scale agricultural projects do not seem to be specifically mentioned.

Forced migration statistics

Assessing the volume of global flows of forced migrants is valuable in identifying trends and the patterns of distribution with respect to where the burden for providing assistance and care lies. In specific countries and contexts, where people are forced to migrate from their place of origin, the first step in addressing public health and other more general concerns is often to define the size of the population at risk. Donors, governments, aid agencies, and community organizations require basic demographic and related data to inform planning and service delivery. The collection of data is complicated and surrounded by controversy, having the potential to immediately reframe what looks like a technical issue into a political one.

The two main sources of statistics on forced migrants are the United Nations High Commissioner for Refugees (UNHCR) and the US Committee for Refugees and Immigrants (USCRI). These organizations produce differing estimates for different types of forced migrants in different geographical contexts. The logistic difficulties of collecting reliable data from shifting forced migrant populations leaves space for political interests to enter, and seek to shape, the field. This is compounded by disagreement over definitions of forced migrants and which groups to include in which categories, as mentioned earlier, with significant implications for the rights and entitlements of such groups, as well as for who bears the responsibilities for addressing their needs. Despite contested data, available sources provide valuable information on trends and distribution.

UNHCR forced migration statistics

The UNHCR provides data based on ‘persons of concern’, an increasingly wide-ranging term. ‘Persons of concern’ includes refugees (as defined by the 1951 Convention or the 1969 Organisation of African Unity (OAU) Convention); persons granted complementary protection (alternative forms of protection for those that fall outside of the terms of the 1951 Convention) and those with forms of temporary protection; asylum seekers who in the year of data collection are still pending a final decision on an application for protection; stateless persons; refugees who returned to their country of origin in the year of data collection; and IDPs (see Table 10.9.2). For the purposes of UNHCR the latter are limited to conflict-generated IDPs to whom UNHCR protection or assistance is extended, but does not include all IDPs.

UNHCR reported that in 2011 the number of forcibly displaced persons exceeded 42 million for the fifth consecutive year (UNHCR 2011). This figure included refugees, IDPs, and asylum seekers. It was estimated that 4.3 million people were newly displaced in 2011 due to conflict or persecution, with 800,000 of these displaced across international borders. This was a 20 per cent increase since 2010 of new displacement. There was also an increase of 700,000 in refugees and IDPs protected by the UNHCR and 7.1 million, three quarters of the UNHCR refugee population, were reported to be in a protracted refugee situation. Developing countries hosted four-fifths of the world’s refugees (UNHCR 2011). The countries of origin for refugees are shown in Fig. 10.9.1. Afghanistan produced the greatest number of refugees followed by Iraq and Somalia. UNHCR statistics demonstrate that the majority of refugees remain within their region of origin.

Table 10.9.2 Persons of concern to United Nations High Commissioner for Refugees (UNHCR 2011)

	2011
Newly displaced	4.3 million
Refugees	10.4 million
IDPs	15.5 million
Asylum seekers	876,100
Stateless	12 million
Resettlement	79,800 ^a
Unaccompanied children	17,700
Protected by UNHCR	25.9 million ^b
Forcibly displaced people worldwide	42.5 million

^a Resettlement—with or without UNHCR assistance—by 22 countries.

^b Protected by UNHCR—refugees and IDPs.

Source: data from United Nations High Commissioner for Refugees (UNHCR), *A Year of Crises: UNHCR Global Trends 2011*, UNHCR, Geneva, Switzerland, Copyright © UNHCR 2012, available from <http://www.unhcr.org/4fd6f87f9.html>.

Pakistan was the country that hosted the most refugees in 2011, followed by Iran and Syria. Almost half of the world’s refugees falling under the UNHCR mandate were hosted in countries with a GDP per capita of less than \$3000.

It is important to note that Palestinian refugees falling under the mandate of the United Nations Relief and Works Agency for Palestinian Refugees in the Near East (UNRWA) are not included in the UNHCR refugee figures, but are included in the 42 million forced migrants. The Palestinian community has been one of the largest groups of refugees that has remained without being fully resettled or absorbed into host-nations; a reflection of how community members on the ground suffer while local, national, regional, and global powers resolve, or fail to resolve, higher-level strategic and political issues.

Given the importance of these numbers, they are invariably contested and debated; with key actors seeking to shape what data are collected and presented, who are counted, and what the implications are for future activities. Indeed each ‘player’ in the system, whether they be a UN or non-governmental agency, a recipient or state of origin, a local community or professional group, and many others, has their own rationale for inflating or deflating the numbers of people whether they be refugees or IDPs, in or outside of camps, dependant or free of other major influences.

Internally displaced persons

The global number of IDPs at the end of 2011 was estimated by the UNHCR to be 26.4 million, with 15.5 million benefiting from UNHCR assistance. The figure for 2011 was the second highest on record, according to the UNHCR this was partly due to displacement from Afghanistan, Côte d’Ivoire, Libya, South Sudan, Sudan, and Yemen (UNHCR 2011). Fig. 10.9.2 shows the distribution of IDPs globally.

Asylum seekers

In 2011, 876,100 applications for asylum or refugee status were submitted to UNHCR offices or governments. One-tenth of all

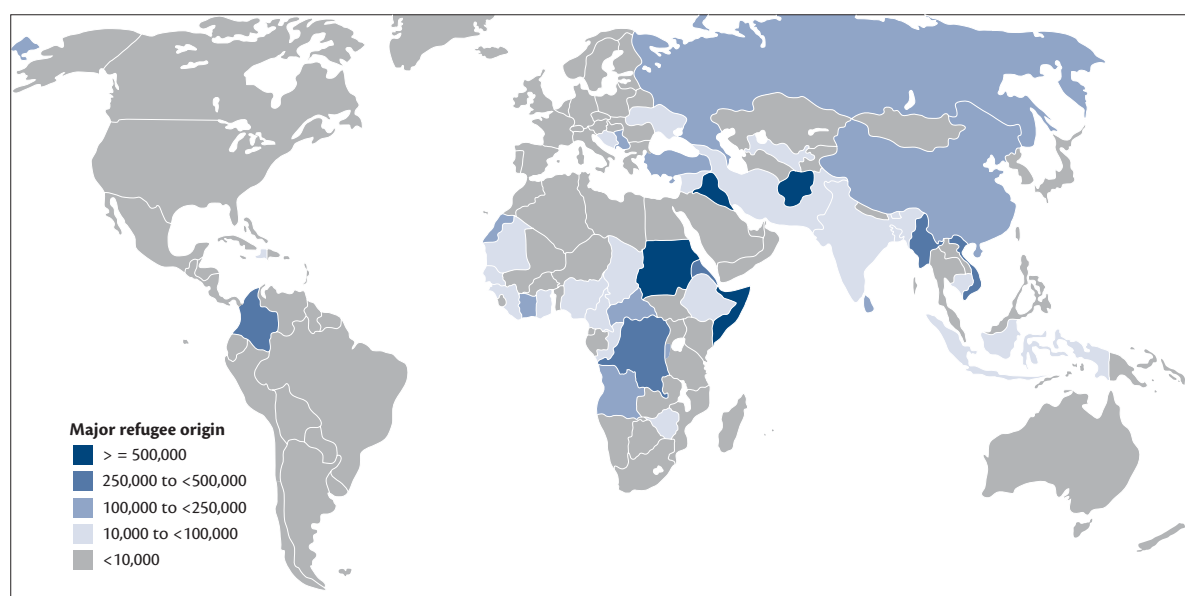

Fig. 10.9.1 Country of origin for refugees under UNHCR mandate 2011.

Reproduced from United Nations High Commissioner for Refugees (UNHCR), *A Year of Crises: UNHCR Global Trends 2011*, UNHCR, Geneva, Switzerland, Copyright © United Nations High Commissioner for Refugees 2012, available from <http://www.unhcr.org/4fd6f87f9.html>.

these applications were registered in South Africa, making it the top asylum destination by a clear margin, more than half these claims were from Zimbabwean nationals. The United States was the next highest receiver of asylum applications with almost half coming from China, Mexico and El Salvador. The UNHCR noted significant differences between countries in recognition rates suggesting differences in how asylum seekers are treated. For example, between eight European countries the recognition rate for Afghan asylum seekers ranged from 3 to 33 per cent (UNHCR 2011).

Legal framework

Refugees

The 1951 Convention, which forms the basis of all international refugee law, was drafted in the aftermath of the Second World War in response to the large numbers of displaced people caused by the war. The Convention included restrictions on who would be classified as a 'refugee' based on geographical and temporal factors that were specific to the European context. As a result, the 1967 Protocol relating to the Status of Refugees was adopted which removed these restrictions and allowed for more general application of the Convention. The Convention and Protocol laid out not only the definition of a refugee but also the scope of protection to which refugees were entitled. The most fundamental of these is *non-refoulement*, the right to remain rather than be returned to a place where their lives or freedoms would be at risk. Debate has raged over the continuing relevance of the Convention definition, given that it excludes large numbers of people in need of international protection, notably internally displaced persons and those that have migrated as a result of generalized (as opposed to individualized) violence, civil war, and widespread human rights abuses.

Africa and Latin America responded to the limitations of the Convention and Protocol by adopting their own regional laws and

standards. The Organisation of African Unity (OAU) (now known as the African Union) adopted the 1967 Convention Governing the Specific Aspects of Refugee Problems in Africa (Barnett 2002). This is the only legally binding regional instrument and has a refugee definition similar to that of the Convention but includes those who flee due to 'external aggression, occupation, foreign domination or events seriously disturbing public order in either part or the whole of his country of origin or nationality' (OAU 1969).

In Latin America, the Cartagena Declaration, adopted in 1984, included a definition of refugee similar to that of the OAU Convention but which also included reference to 'massive violation of human rights' (Regional Refugee Instruments & Related 1984). The latter is not legally binding but has been adopted by many states and incorporated into some national legislation in the region.

Persons who have participated in war crimes and violations of humanitarian and human rights law, including the crime of terrorism, are specifically excluded from the Convention and cannot be recognized as refugees.

The UNHCR has been given a mandate to provide international protection to refugees and seek permanent solutions to their problems through its Statute, adopted by the UN General Assembly (UNGA) in December 1950. Over the years, the UNGA has allowed UNHCR to extend its responsibilities and is increasingly focused not only on refugee protection but also on managing refugees in the field.

Internally displaced persons

Whilst IDPs do not have the same legal framework of protection, they have become included in the UNHCR's 'people of concern' and are therefore often covered by its mandate. The United Nations Office for Coordination of Humanitarian Affairs (OCHA) has produced a set of Guiding Principles to address the specific needs of internally displaced persons (Deng 1998). The guidelines

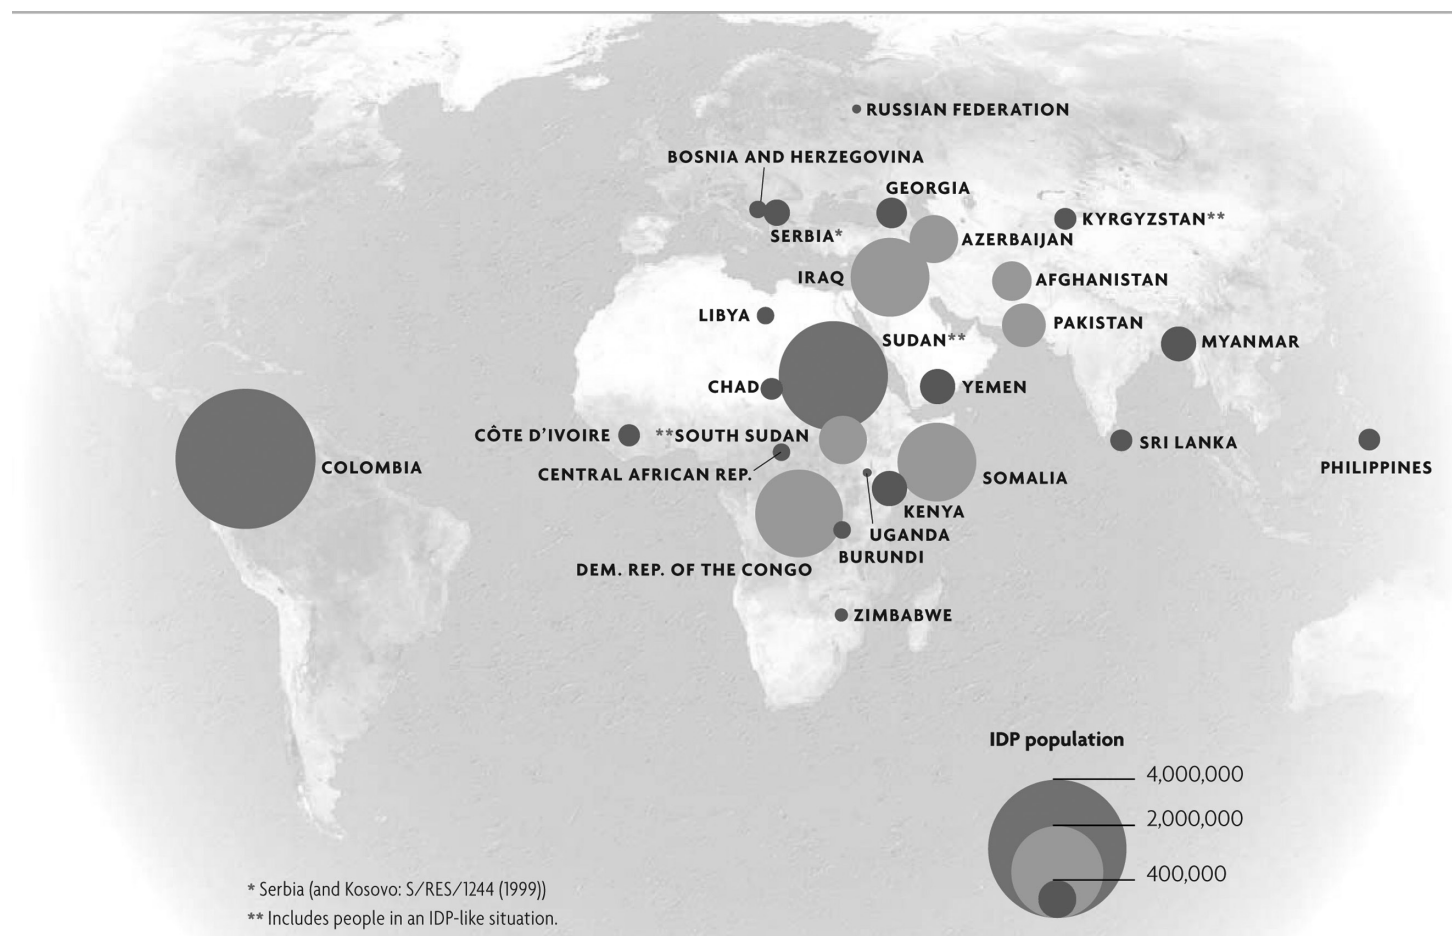

Fig. 10.9.2 Distribution of IDP populations globally 2011.

identify rights and guarantees that should be afforded to IDPs although they are not legally binding.

Asylum seekers

The Declaration of Territorial Asylum (DTA) adopted by the UNGA in 1967 is based on article 14 of the Universal Declaration of Human Rights, which declares that ‘everyone has the right to seek and to enjoy in other countries asylum from persecution’. The principles of the DTA are that all States recognize asylum granted by one State, that States themselves evaluate the grounds for asylum, and that no one seeking asylum should be rejected at borders or if already within a country should not be compulsorily returned to any State in which they may be subject to persecution. Exceptions can only be made in situations of national security or for asylum seekers that have committed a crime against humanity, against peace or a war crime.

Asylum may be granted by States on the basis of the 1951 Refugee Convention, in which an individual has been deemed a ‘refugee’ as defined by the Convention. However, given the restrictions of this definition and the increasing numbers of people who are seeking protection but do not fit the Convention definition, alternative forms of protection have developed. Often termed ‘complementary’ or ‘subsidiary’ protection, McAdam (2006) describes the plethora of alternative forms of protection for ‘non-Convention refugees’ that previously had been treated much the same as Convention refugees by states.

‘Non-Convention’ refugees, such as those fleeing widespread violence rather than targeted individual persecution, have to look to instruments of human rights law, rather than refugee law, for protection. However, human rights instruments do not attach the same clear rights and standards as the Refugee Convention and it has also been argued that human rights law can be weak on implementation (McAdam 2006). This has led many to argue that complementary protection is a lesser form of protection, and there is a danger of States using these forms of protection to decrease the numbers of Convention refugees and therefore their level of commitment. Debate continues as to whether expanding the current Convention definition, or expanding systems of complementary protection, will weaken or broaden protection to those seeking asylum.

Trafficking and smuggled persons

Although the reasons for a person to be trafficked or smuggled are very similar, international agreements and national laws treat them quite differently. Unlike trafficking, which may occur internally in a country, smuggling always involves the illegal crossing of an international boundary. Smuggling is seen as a crime against a *state* whereas trafficking is a crime against an *individual*. Consequently persons that are trafficked or smuggled are likely to be treated quite differently. The UN Convention on Trafficking mandates states to consider granting victims permanent or temporary resident status, whereas the Smuggling of Migrants Protocol calls on states to facilitate the return of smuggled persons to the country from which they came.

Environmental and developmental displacees

The concept of environmental refugees or displacees is particularly contentious and the subject of much current debate. There

is little agreement on whether environmental factors can be seen as primary causes of displacement and equally no consensus on a definition for those displaced from their homes by these factors. As a result the legal protection available is marginal. The current legal regime has no specific mandate to protect environmental displacees, if they are displaced across international borders; however, ‘natural or human-made disasters’ are covered by the Guiding Principles on Internal Displacement (Deng 1998). These place the primary duty for protection with the national authority; however, no duty is placed on other states to recognize the need for protection. A growing body of opinion has begun calling for a system of global governance that recognizes environmental factors as a cause of displacement and for the displacees to be protected under international law (Courtland Robinson 2003; Biermann and Boas 2007).

Similarly, developmental displacees do not have frameworks of protection of their own but are covered by the Guiding Principles on Internal Displacement. There is a need to recognize the needs of this group and for research on displacement not to fall into a dichotomy that separates conflict-related displacement from development-related displacement (Cernea 2007).

Evolving rights of protection

Protection based on a definition of refugees fleeing from the effects of violent conflict has been the prevailing paradigm, and whilst the centrality of conflict-related displacement has been debated, conflict and violence clearly remain significant causes of forced migration and suffering. Analysis reflecting the increasingly complex drivers of forced migration, including economic and environmental concerns, whilst vital, should be careful not to compromise existing rights of protection. These rights of protection, based on conflict as the central tenet, should not be further eroded by the recognition that there are other causes of forced migration that need to be seriously considered.

Public health situation of forced migrants

Forced migrants live in a range of different social, political, and geographical conditions. They may form distinct populations or be dispersed amongst host populations; they may be displaced within their own country, to a nearby or distant country of asylum; and may dwell anywhere from a developing country experiencing conflict, to a more peaceful but poverty-stricken developing country, to a wealthy developed nation. The health of each forced migrant population, and each individual within the group, will be shaped by these factors, as well as their prior health and social condition, the journeys they have had to take, the stability and security present in their new environments, the social structures within which they live, and the access they have to services and social support.

Gushulak and MacPherson (2000) describe migration health in terms of ‘three distinct but interdependent undertakings: The pre-departure phase, the migratory journey itself, and the arrival at destination’, each of which influences health. Factors such as social networks, assets, language, knowledge, information or access to services, food security issues, poor shelter, sanitation, and availability of safe water will influence health outcomes.

In this section we describe the major health challenges facing forced migrant populations. This is followed by an overview of the

public health responses and an indication of where more detailed technical advice may be found.

Refugees in developing countries

Developing countries continue to absorb the vast majority of forced migrants, in particular as developed nations have become more restrictive. Within developing countries, people who are forcibly displaced either within or across borders may find themselves in a variety of possible contexts, settling short or long term either in a camp situation or dispersed within a host population. Each presents threats and opportunities.

The type of settlement formed has implications for health and well-being. The typical refugee camp setting has presented a range of problems, although improvements in public health knowledge and experience, and informing policy and practice with evidence, have led to better outcomes.

The impact of forced migration falls heavily on developing nations, and within these countries, on host populations. This is particularly so where forced migrants reside in non-camp situations.

Camps and non-camp settlements

Camps, whilst constructed with the intention of providing protection, safety, and access to services, may also pose risks. Poorly planned refugee settlements may have inadequate infrastructure, may pose risks to safety, or set up new inequalities. The combination of overcrowding, poor hygiene and sanitation, lack of water, poor nutrition, and inadequate shelter provides conditions for spread of many diseases, particularly communicable disease. Refugees may arrive in a poor condition, suffering from malnutrition, and with poor immunity, reflecting limited access to immunization services. Disrupted social structures decrease the capacity to deal with sickness. Communicable disease spreads quickly and may be particularly severe. Psychological distress is also a major issue due to the insecure, restricted environment and lack of resources.

Debates over the utility of camps are highlighted by Harrell-Bond (2000) who argues that as a concept they have failed. Originally based on modernization theory, the premise was that camp settlements would become new agricultural centres and eventually be integrated with host populations to the benefit of all. However, this was abandoned as the theory became discredited and was replaced by a view that refugees should be seen as temporary. Harrell-Bond suggests that those in camps are in 'prison-like' settlements with poor conditions, increased vulnerability to disease and often poor nutrition. She also argues that camps do not help host populations, as large sums of money are diverted to camps which may be demolished if refugees do move on, as well as diverting scarce human and material resources from the host population. She suggests that it would be far more appropriate and cheaper to help integrate refugees into host populations and invest in the country and strengthening existing social structures, as a whole.

In many situations of forced migration, for example, when the Kosovar Albanians fled from Kosovo over the border into Albania, integration with host populations there was the norm. Following political instability and violence in Timor-Leste in 2006, 4 years after independence, makeshift camps were established within Dili, the capital city, for IDPs, while many also

fled and were integrated with host communities in the districts. The latter necessarily absorbed a portion of the social and economic costs associated with accommodating those who fled.

However, Salama et al. (2004) show that, despite the problems associated with camps, there are also benefits. The increased knowledge base and coordination of humanitarian interventions have led to improvements in health, with better nutrition, sanitation, and health services. The burden of ill health may shift from displaced populations who are relatively well serviced, especially if they cross international borders and become refugees, relative to host populations and IDPs whose needs may be greater and who have less access to assistance.

Mortality

Crude mortality rates (CMRs) are often used as an indicator of the immediate impact of complex emergencies. Toole and Waldman (1990) proposed a definition of the acute phase of a complex emergency as greater than one death per 10,000 people per day, based on a doubling of the baseline mortality rate in sub-Saharan African countries. Surveillance systems to monitor the impact of emergencies have been established in the past 15 years based on this definition. In recent decades, it has not been unusual to see CMRs in refugee populations of 30 times the baseline in the country of origin (Toole and Waldman 1997); some of the highest recorded were amongst Rwandan refugees who flooded into North Kivu in 1994 where average crude mortality rates were 20–35 deaths per 10,000 (Salama et al. 2004). In refugee camps, CMRs of 2 per 10,000 are now rarely seen; however, the situation in non-camp situations has deteriorated (Salama et al. 2004). Refugees are usually at greatest risk in early days of displacement, with mortality rates subsequently diminishing. The highest risk group is young children with most deaths occurring in the under-5 age group, demonstrated dramatically in one Somali camp in which 70 per cent of children under 5 appear to have died over an 8-month period (Moore et al. 1993; Toole and Waldman 1997).

Causes of death

The main causes of death in developing country refugee situations are similar to those of developing country populations in general. The most common causes of death in Africa are diarrhoeal disease, measles, acute respiratory infections, and malaria (where endemic), exacerbated by a high prevalence of acute malnutrition (Toole and Waldman 1997). These diseases typically account for the vast majority of reported deaths in refugee populations, at times up to 95 per cent thereof. This is in contrast to European countries affected by war, where the most common causes of death are injuries, as well as communicable diseases, neonatal problems, and nutritional deficiencies. Recent analyses suggest that chronic diseases require attention, given the ageing population, and violence, instability, and forced migration in populations in which communicable diseases have been relatively well controlled and chronic diseases have emerged as problems (Chan and Sondorp 2007).

The conditions affecting refugees may have been brought with them from the country of origin, may be acquired in the host country (with refugees susceptible due to lack of sufficient immunity), or may result from the camp conditions themselves.

Diarrhoeal disease

Possibly the greatest threat to life amongst refugees is diarrhoeal disease. The main pathogens of concern are usually cholera and shigella. In some refugee camps, more than 40 per cent of deaths in the acute phase of an emergency can be attributed to diarrhoeal disease, and over 80 per cent of these deaths are in children under the age of 2 years (Salama et al. 2004). Outbreaks are exacerbated by factors such as the sharing and contamination of water sources and food, the scarcity of soap, and inadequate sanitation.

Amongst Rwandan refugees in camps in North Kivu, 85 per cent of the 50,000 deaths amongst the 800,000 people that flooded into the area in early July 1994 were caused by diarrhoea, with 40 per cent from shigella dysentery and 60 per cent from cholera (Salama et al. 2004). The primary drinking source, which was lake water, became rapidly contaminated, and as water was also scarce, infection spread swiftly through the refugees. Deaths in Goma were associated with a number of preventable causes (Siddique et al. 1995). Among Kurdish refugees, 70 per cent of deaths were a result of diarrhoea (Toole and Waldman 1997). In the elderly and young children, dysentery case-fatality rates can be as high as 10 per cent. Important public health interventions include the need to supply sufficient water, control excreta and hygiene, and increase public awareness of basic rules of hygiene. Evidence-informed case management is necessary to avoid unnecessary deaths.

Measles

Another of the most feared diseases in camps is measles—a particularly large problem in refugee situations in the 1970s and 1980s until it was recognized that vaccination should be accorded priority. The risk of death from measles is exacerbated in the presence of malnutrition, a common occurrence amongst refugee populations, as are secondary complications. Globally, measles kills hundreds of thousands of people each year. In 2000 there were 562,000 measles deaths but with improved surveillance and vaccination rates this was reduced to 122,000 deaths in 2012 (WHO 2012). While it is less of a problem in previously well-vaccinated populations, in developing countries, measles death rates can range from 1 to 5 per cent, and in refugee settings among malnourished children, the death rate may reach 10–30 per cent.

In 1985, 53 and 42 per cent of refugee deaths in eastern Sudan and Somalia, respectively, were caused by measles (Salama et al. 2004). The situation has improved in refugee camps due to mass vaccination, but IDPs still suffer as they have less access to vaccinations and, since 1990, it is more common to find high rates of measles in IDPs than in refugees. Measles is included in the Expanded Program on Immunisation but there is often low coverage in young children especially where human resources for health are limited or conflict affects normal service delivery. Increasing attention is being devoted to ensuring that services can continue to be supplied in fragile states.

Malaria

In areas where malaria is endemic, it can cause high rates of mortality and morbidity amongst refugees. This is particularly the case when people are displaced from an area of low endemicity to one of high endemicity. Drug resistance also plays a large part with chloroquine resistance and more recent resistance to fansidar reported in Rwandan refugees in Zaire. Local communities

in low endemic areas may be placed at risk by refugees arriving from high endemic areas, especially if local conditions favour the mosquito. In Africa, 30 per cent of annual malarial deaths occur in complex emergency settings. This is because in complex emergencies (CEs) overcrowding increases the frequency of bites and also delays intervention thereby increasing the time that the parasite is in the blood (Salama et al. 2004). An example is Burundi which had a major epidemic in 2000–2001 when the population of 7 million reported 2.8 million cases of malaria, the war in 1993 caused control efforts to break down, populations were moving, and there was widespread resistance to chloroquine.

Acute respiratory infections

Refugee camp conditions facilitate the spread of acute respiratory infections (ARIs) and rank amongst the leading causes of death in displaced populations. The lack of shelter, overcrowding with poor ventilation, and exposure that characterize the refugee existence contribute to the susceptibility to ARIs with poor outcomes. Young children are particularly affected. In Kabul, in 1993, 30 per cent of under-5 deaths and 23 per cent of deaths in displaced persons were a result of ARIs (Salama et al. 2004). Vaccinations against malaria, diphtheria, and pertussis have led to decreased mortality from ARIs. It is not just that these pathogens cause ARIs but they also render hosts less able to defend themselves from bacterial infection.

Tuberculosis

Tuberculosis (TB) is becoming increasingly important in complex emergencies and situations of forced migration—in part as a result of disrupted therapy (Connolly et al. 2004). TB can become a major problem, leading to a large numbers of deaths. Poor nutrition and over-crowding exacerbate the risk of TB, as may underlying HIV in some populations. A recent study of instability and internal displacement in Timor-Leste revealed a number of problems in maintaining continuity of treatment for those with TB. As a result, many may have incomplete or inadequate treatment.

Meningococcal disease

Meningococcal disease is a potentially major problem for refugees when they are in overcrowded settlements in an endemic area, such as the ‘meningitis belt’ of sub-Saharan Africa that stretches from Senegal to Ethiopia. In Africa, a threshold incidence of 15 cases per 100,000 population per week is used to define the presence of an ‘epidemic’. In CEs, large epidemics have also been reported outside the traditional malaria belt. The Democratic Republic of the Congo had six epidemics in 6 months in 2002 and epidemics have also occurred in Uganda, Rwanda, and Tanzania (Salama et al. 2004). Immunization has proved to be an effective control measure but is only effective in epidemics, routine immunization is not effective as the current vaccines only produce immunity for 3–5 years and may not be used in children under 2 years. Therefore, the World Health Organization (WHO) only recommends mass immunization in areas where epidemic proportions have been reached, and they estimate that this can reduce deaths by up to 70 per cent.

Hepatitis

Outbreaks of hepatitis E have occurred in African refugee camps. It is transmitted by the entero-faecal route, and therefore water

supplies are often involved. Case-fatality rates vary from 1–4 per cent but there have been particularly high attack rates and case-fatality rates (up to 20 per cent) reported amongst pregnant women. The high level of previous exposure to hepatitis A and B in developing countries makes it likely that any hepatitis epidemic with high attack rates in adults is likely to be caused by hepatitis E.

HIV/AIDS and other sexually transmitted infections

The pattern of HIV/AIDS and sexually transmitted infections (STIs) amongst refugee populations in developing countries will depend on many factors, including the level of infection prior to displacement (Dualeh and Shears 2002). Spiegel (2004), working at the UNHCR, has highlighted the key preventive and other responses to HIV/AIDS. Conflict situations and camp conditions have often been thought to exacerbate the spread of STIs, due to breakdown of social structures, behavioural change, sexual violence, and lack of access to services and testing (Zwi and Cabral 1991). However, Spiegel (2004) describes other factors inherent in refugee situations that may retard the spread of these diseases, such as decreased mobility, and the possibility of a host country having increased services in comparison to the country from which people have fled. He argues that each situation should be examined independently and that the spread of STIs is most likely to be determined by the complex interactions between a number of groups: refugees and their hosts, the original conflict-affected population, IDP populations in the country of origin, and host communities in country of origin. He argues for public health responses to be broad and focus not only on camps but the entire situation, including host populations.

Other communicable diseases

Outbreaks of other less common communicable diseases have been reported in some refugee camps, as highlighted by Dualeh and Shears (2002). Typhoid fever is endemic in many tropical areas and may occur sporadically in refugee situations. Leishmaniasis and trypanosomiasis have also been reported in epidemic proportions amongst displaced populations in Uganda and Sudan. Viral haemorrhagic fevers occur in selected areas and may place refugee communities at risk. Rift Valley fever has been documented among Somali refugees in Kenya, yellow fever occurred amongst displaced populations from Ethiopia to Sudan, and dengue fever affects refugees in endemic areas of South East Asia.

Connolly et al. (2004) provide an excellent overview of the literature on communicable diseases and complex emergencies.

Malnutrition—protein energy deficiencies

Moderate to severe acute malnutrition is a common occurrence in refugee settings. Children are particularly affected, with some deteriorating in terms of nutritional status after arrival in camps, due to inadequate nutrition or diarrhoeal disease. Surveys undertaken between 1988 and 1995 documented a range of 11–81 per cent of children under 5 years suffering acute malnutrition in conflict affected populations (Toole and Waldman 1990). Acute malnutrition can be both the cause and effect of other illnesses, and

contributes to mortality both directly and indirectly. Malnutrition and measles are particularly linked with malnutrition exacerbating measles, and measles itself contributing to high malnutrition rates in those that survive it (Toole and Waldman 1990). This ‘synergistic relationship’ that malnutrition has with communicable disease requires an integrated response aimed at improving nutrition combined with efforts to improve public health services.

Micronutrient deficiencies

As a result of inadequate food rations micronutrient deficiencies occur frequently in refugee populations. The most common diseases seen are iron and vitamin A deficiencies but other diseases include scurvy (vitamin C deficiency), pellagra (niacin and/or tryptophan deficiency), and beriberi (thiamine deficiency). As Prinzo and Benoist (2002) discuss, the solutions are not simple and each setting may require a different approach, including providing fortified blended cereal and finding ways to exchange rations for locally produced fresh fruit and vegetables.

Food and nutritional interventions need to be responsive to cultural as well as economic issues.

Reproductive health

The reproductive health needs of refugees have gained recognition since the mid 1990s. The burden is undeniably greater for women as a result of insecurity in their social situations and gender-based violence. Women lack basic necessities such as sanitary napkins and condoms, and pregnancy itself can be a serious health threat in settings in which services are lacking or overwhelmed (Krause et al. 2000). Referral services are often non-existent and birthing or abortion may be undertaken in unsafe situations. Women may have no, or limited, access or means to carry out family planning, rape and sexual coercion are typically increased, and there may be pressures on women to rebuild the population. Female genital mutilation may occur and STIs, including HIV, may be relatively common (Krause et al. 2000). A particularly important set of risks relate to sexual and other forms of gender-based violence, common in all societies and increased where societal norms are less able to be enforced or reinforced, and in which men with guns can demand whatever they like in return for precious resources such as safety, food, and onward passage. Intense efforts have focused on improving all aspects of reproductive health for women affected by complex emergencies and forced migration—and a Minimum Initial Services Package has been produced to address these needs. A study by Hynes et al. (2002) showed that due to the strength of the response there have actually now been better reproductive health outcomes in refugee camps than in host population or origin countries. However, the lessons learned require expansion across settings.

Mental health and psychosocial needs

Mental health problems are recognized as an important source of morbidity globally (Prince et al. 2007) and are likely to be even greater amongst displaced populations. Epidemiological assessments have documented high rates of mental illness in these populations. Studies have tended to focus on trauma-related conditions, although low prevalence conditions such as psychosis have also proven significant in post-conflict and refugee settings. There is

much debate about the validity of Western-derived measurement and about the trauma focus, with further development of relevant culturally valid ways to measure psychiatric morbidity still required. Despite the measurement debate, there is clearly a substantial burden of mental distress in these settings, and support for vulnerable people is vital in situations of social breakdown, especially where usual systems of social support and healing are disrupted (Silove et al. 2000a). It may be of value to identify and respond to the needs of three different groups of people who experience psychosocial and mental distress in these situations: those who are mentally ill, who need treatment; those who have had particularly horrific experiences and need care and support in order to recover; and what tends to be the majority who need a more stable social and political environment in which they can resume their normal day-to-day activities necessary to promote mental health.

Internally displaced persons

While IDPs in developing countries have very similar health problems to refugees, they also have particular vulnerabilities. Some of these result from falling through gaps in a system geared to protect a particular group of forced migrants (i.e. 'Convention refugees'). Particularly in developing countries, but also in more developed states, the limited data available suggest higher morbidity and mortality in IDPs compared with refugees (Salama et al. 2001). With limited protection granted by the international community, the responsibility for protection and assistance often lies with their own governments. Yet, it is these governments themselves that have often contributed to the displacement experienced. Governments may not even officially recognize the existence of IDPs for fear of international scrutiny or interference. A growing number of countries have developed laws and policies to govern responses to IDP populations but not all make concerted attempts to implement these policies, and even when there is political will the states involved are often the poorest countries of the world, limiting their ability to respond. There is no mandated international body although UNHCR may include them amongst their persons of concern and they are increasingly supported by agencies which follow the UN's Guiding Principles on Internal Displacement (Deng 1998).

IDP populations rarely experience access to health services at the same standard as offered to other citizens and are likely to be markedly poorer than those available to refugees. Recent efforts to improve quality and responsiveness of interventions in humanitarian crises and complex emergencies have contributed to better health outcomes. IDPs, however, have poor access to these improved systems of protection and assistance.

Collection of data is more difficult amongst IDP populations and relatively few studies focus specifically on IDPs. However, the IDP-specific health data that are available suggest that access to healthcare for IDPs is often extremely limited. Salama et al. (2001) show how some of the highest mortality rates in humanitarian emergencies have been found in IDP populations; Sudan and Somali, for example, reached 8 per 10,000/day and 17 per 10,000/day respectively (Salama et al. 2001). In Ethiopia and the Democratic Republic of the Congo, delays in vaccinations led to measles outbreaks. In Ajiep (southern Sudan), severe acute malnutrition amongst IDPs reached 36 per cent during a famine in 1998.

Although international humanitarian law applies to all civilians affected by armed conflict and therefore IDPs should be afforded

the same protection and assistance as the un-displaced host population, there may be multiple reasons why IDPs face discrimination and therefore do not receive the help they need.

Even in developed countries IDPs may have poor health outcomes. They are often subject to the discrimination and exclusion experienced by their developing country counterparts. The Internal Displacement Monitoring Centre (IDMC) describes the situation for a number of IDP groups in developed nations:

While IDPs in the Balkans generally have satisfactory access to water, sanitation and healthcare, they are more likely than the local population to suffer from trauma-related problems. Roma IDPs usually live in informal settlements with very poor sanitary conditions. IDPs in Azerbaijan and the Russian Federation access healthcare less easily than the local population in some areas, due to administrative inconsistencies, lack of healthcare facilities and the demand for informal payments for medical treatment. (IDMC 2008)

IDPs, whether in developing or developed countries, are clearly living with a higher burden of illness and mortality than many other forced migrant groups. Initiatives are emerging that aim to support this extremely vulnerable population, but they are yet to be supported by any legal framework.

Refugees and asylum seekers in developed countries

Refugees and asylum seekers often reach destinations in developed countries after long, precarious journeys. Prior to the journey, they will have faced many of the routine health problems that present themselves in disrupted developing country settings. The journey itself will have produced health challenges; people may have been detained at points along the way or experienced significant anxiety and distress through difficult and dangerous journeys and experiences. On arrival, the range of situations they find themselves in will further shape their health condition. Those who have applied for refugee status prior to arrival may have undergone health checks already in the country of origin, as is the practice of many developed countries; therefore, certain health conditions may have been picked up. Depending on the country they arrive in, they will then have a different range of options available to address their health problems. However, those applying for refugee status on arrival have an even more complicated journey; they may be detained for short or long periods, they may have extensive periods on temporary visas or they may find themselves living illegally without authorization from the host country. Typically asylum seekers are often isolated with difficulty in communication, in a situation of poverty, discrimination, and a lack of social structure, causing many to suffer from trauma-related problems and many general health problems, exacerbated by poor provision of health information and barriers to accessing services.

Biggs and Skull (2003) discuss the specific medical conditions that may be present amongst refugees in developed countries. These include communicable disease such as TB, HIV, STIs, hepatitis B and C, and parasitic diseases, all compounded by incomplete immunization. In addition, nutritional deficiencies (vitamin D in particular), mental health problems, and other non-communicable diseases such as diabetes and reproductive health issues are common.

Screening for health problems among newly 'arrived' refugees, or prior to arrival for those applying for refugee status overseas, is common practice. Biggs and Skull (2003) point out that there is

little evidence demonstrating that screening has proved effective as many people have limited contact with services and many are lost to follow up. Refugees seeking asylum in the United States are screened before arrival to identify 'inadmissible conditions' such as HIV, TB, and leprosy. They may also be screened for diseases that are known to be prevalent and targets of public health intervention. For example, Somali refugees were mass treated for malaria and intestinal parasites. The types of health problems sought and treated in newly arrived immigrants also reflect particular areas of concern for asylum seekers, including infectious disease, gynaecological health (rape, genital surgery, STIs), and mental health (torture, trauma) (Adams et al. 2007).

Burnett and Peel (2001) evaluated the health needs of asylum seekers and refugees in Britain. They point out that these groups are subject to 'poverty, dependence, and lack of cohesive social support' as well as racial discrimination. They consider a range of studies examining the health status of refugees and found, for example, that 21 per cent of migrants to Spain from sub-Saharan Africa were chronic carriers of hepatitis B, and 3.4 per cent of refugees arriving in the United States in 1988 had TB. They highlight the lack of screening programmes available and how the focus has tended to be on protecting hosts rather than a responsibility to provide healthcare to all.

One specific refugee and asylum health condition that has been investigated somewhat more extensively than other health issues is mental health (see Chapter 8.7). Gerritsen et al. (2004) describe how early research focused on those who used services, or victims of trauma, followed by early population-based studies in Western settings which have tended to focus on psychiatric disorders such as post-traumatic stress disorder (PTSD), anxiety, and depression. In a review of the literature, Fazel et al. (2005) show documented rates of PTSD of 4–70 per cent, depression 3–88 per cent, and anxiety 2–80 per cent. Their meta-analysis suggests that one in ten refugees in Western countries have PTSD, one in 20 has major depression, and one in 25 has a generalized anxiety disorder. Although lower than some estimates, this is still ten times higher than rates of PTSD in the general population in the United States. Data for asylum seekers alone is sparse but there are reasons to believe they have even higher rates due to their vulnerability because of disruption, separation from family members, increased levels of torture and trauma, lack of language skills, and the often hostile reception from host population fuelled by media perceptions. The current trend towards detention, and temporary rather than permanent protection have added extra stress, as evidenced by studies of asylum seekers in detention centres and on temporary protection visas showing very high rates of mental illness (Silove et al. 2000b, 2007).

Problems that asylum seekers in particular face, rather than refugees, relate to issues of having a temporary and often contested legal status, and in some cases being considered illegal, with implications (real or perceived) for access to health services. Many countries such as the United Kingdom and Australia have fluctuating policies with regards to what asylum seekers, of differing categories, may be entitled to in terms of healthcare. This can act as a barrier to health for many asylum seekers. The increased use of detention for asylum seekers, whilst claims are processed, has been challenged heavily by health professionals as a result of evidence that it is detrimental to health. The other popular policy of extending only temporary protection to some asylum seekers,

therefore also causing confusion with regards to health entitlements, and long-term insecurity with associated health risks, has also caused concern to health professionals (Silove et al. 2000b). Australia has passed legislation to allow off-shore processing for asylum seekers. A policy of this kind raises more complex questions in terms of entitlement and availability of healthcare. Health professionals have called for screening to ensure those with the most severe mental and physical health problems are identified and if necessary processed on the mainland.

Healthcare for asylum seekers may be difficult to access on many levels: policies of active deterrent of asylum seekers may mean they are not entitled to care, or there may be lack of prioritizing refugees; health professionals often misunderstand what the policies are and may refuse to register asylum seekers, they also fear the burden of vulnerable groups; those that do offer treatment may lack understanding of the refugee health situation; temporary registration with GPs may be offered rather than permanent (limiting access to immunizations and screening); and language problems are also a great barrier, with many practitioners having inadequate access to interpreting services.

Harris and Telfer (2001) estimated that in 1999–2000 there were over 10,000 asylum seekers living in the community in Australia. Many had to survive for many months or years with no right to work and no medical cover through the national Medicare scheme, resulting in untreated medical conditions. A study in Sydney suggested that most presenting to an Asylum Seeker Centre providing health services had fairly serious psychological or physical symptoms. Some related to trauma and torture, others were infectious diseases, musculoskeletal complaints, and gynaecological problems. Up to 40 per cent of the asylum seekers were denied Medicare. A few are picked up by the Asylum Seeker Assistance Scheme and the Red Cross assists others. Hospital fees are particularly high and case studies have shown that some people are denied hospital treatment until assurance of payment is provided.

Trafficked and smuggled people

People that are trafficked or smuggled are not an entirely distinct group from other types of forced migrants already described. Trafficked people have been coerced or tricked into allowing another person to organize their passage to another country; also smuggled across borders are those who 'voluntarily' migrate for a vast range of reasons but feel unable to do so through legal channels. Although these groups may appear distinct from refugee populations they may include Convention refugees and others whose circumstances are very close to those of refugees. Resorting to illegal and clandestine methods of migrating to another country, either through being coerced and misled or through having such limited choices as to choose this route, is often a result of many of the factors behind the forced migration of refugees and internally displaced people.

Gushulak and MacPherson (2000) describe some of the reasons why people may fall into a trafficking situation. Poverty, exposure to violence, restrictive barriers—for example, screening for certain diseases or security barriers, slow processing of routine immigration applications which may cause delay to family reunification—all may encourage people to take alternative routes—especially when traffickers may offer what appear to be attractive possibilities. They state that the reasons why someone is more likely to migrate through these illegal methods are also reasons

that place a person at higher risk of having poor health prior to migration. The journeys faced by trafficked and smuggled people are often extremely precarious, with high levels of morbidity and mortality attached as a result: unseaworthy and overcrowded boats on long journeys, stowed in containers, attached to carriers, attempts to cross inhospitable land with extremes of temperature, drowning from swimming attempts, violence from traffickers, and illegal activities such as smuggling drugs with people. On arrival people are then subject to many of the difficulties already outlined that face asylum seekers. Some trafficked and smuggled people may seek asylum and depending on the policies of the countries may incur some health benefits; however, many will be forced into illegal employment and be either too scared to make or prevented from making an approach to health services. Disease prevention and control in this population will be extremely poor—leading to increased prevalence of disease in the trafficked community as a whole.

Busza et al. (2004) examine the need for careful understanding of trafficking situations and to unravel the local dynamics. They state that even when intermediaries are involved, and even when they are taking people into exploitative arenas such as sex work, these situations remain a complex mixture of voluntary and forced migration. Whilst economic disadvantage may fuel the choice, there is still a choice being made in some contexts and organizations seeking to stem the flow or break up these systems may compromise the health or the individuals involved more than they help. Attempts to ‘save’ people may make them even more vulnerable—for example, the raiding of brothels and other such moves can force vulnerable people to go underground making engagement with health services difficult.

The health of trafficked and smuggled people is affected by the fact that they cannot easily be separated out from each other or from other types of ‘voluntary’ migration that are not truly voluntary but have strong forces pushing people on. The policies developed by states towards any of these groups are likely to impact on the capacity of other groups to access healthcare. Displaced people are more vulnerable to trafficking and may in desperation turn to smugglers. This should be kept in mind by health professionals to avoid vulnerable people missing out on essential services and support.

Public health solutions and interventions

Forced migration clearly has major impacts on public health. Specific solutions and interventions need to be sensitive to culture and context, and include a critical assessment of the political dynamics that may affect how assistance is actually received and impacts on the lives of forced migrants. Harrell-Bond et al. (1992), the doyens of analysts examining forced migration, along with other key commentators such as Crisp (1999) and Bakewell (n.d.), demonstrate how resources to deal with forced migration are structured by broader ideological, political, and economic decisions. Harrell-Bond et al. (1992) argue that refugee camps and many of the structures and organizations set up are part of a system of control of those in need. She argues that the allocation of resources (whether aid, political or military resources) is a ‘central component in an ideology of control’. The granting of aid often legitimizes a group and their struggles; politics influences the status and visibility accorded to different groups. Even where humanitarian and development assistance are well targeted

at forced migrants in need, the impact of services, systems, and funds, may be both positive and negative. While the forced migrants in great need may be able to access resources, these are not distributed equitably, and local populations, which often bear the brunt of providing for such community members, frequently are marginalized and unable to access new resources or services.

A valuable compilation of insights (Essed et al. 2004) highlights how forced migrants interact with agencies and the implications for ethics, policies, and politics. A case study by Turner (2004) in the same volume, for example, demonstrates how UNHCR effectively displaces older men as providers in their families and in so doing creates new dependencies. UNHCR becomes ‘a better husband’—at the same time undermining and transforming traditional household and family relationships. These political complexities are vital to keep in mind when planning and implementing a public health response with vulnerable communities.

Key actors and organizations in refugee health

There is an extensive range of organizations involved in addressing forced migration. The UN has designated the UNHCR as the key multilateral agency for identifying and dealing with refugee issues. More recently, the mandate of UNHCR, as described earlier, has been extended to include other ‘people of concern’ including IDPs and asylum seekers. Other agencies with a specific mandate for dealing with forced migrants include the International Organisation on Migration, the International Centre for Migration and Health, the American Refugee Committee International, the US Committee on Refugees, and the Global IDP Project.

A wide range of multilateral agencies including the WHO, UN Population Fund (UNFPA), UNICEF, International Committee of the Red Cross (ICRC), International Federation of Red Cross and Red Crescent Societies (IFRC), and UNAIDS has some concern with forced migrants. Key non-governmental organizations (NGOs) include Merlin, Médecins Sans Frontières (MSF), International Medical Corps (IMC), International Rescue Committee (IRC), OXFAM, Save the Children Fund, CARE, Caritas, CONCERN, and the Norwegian Refugee Council. Academic bodies include the Oxford University Refugee Studies Program, the Centers for Disease Control and Prevention (CDC), and the Refugee Studies Program in Cairo. A number of important journals, notably the *Journal of Refugee Studies*, *Disasters and Conflict and Health*, and the website of Forced Migration Online, provide avenues for academic debate.

Developing countries and complex emergency settings

The principles of public health and epidemiology only began to be systematically applied to complex emergency situations from the early 1970s (Salama et al. 2004). Since then, new academic and practitioner fields have developed, including emergency public health and public health nutrition. With the introduction of an indicator to measure the impact of a complex emergency through CMRs, alongside the development of simplified measurements of malnutrition, and threshold rates for epidemics, it has become increasingly possible to draw meaningful inferences from data collected.

An understanding of the dynamics of disease and related mortality in CEs has grown, and practice improved on the basis of

experience and research evidence. Guidelines and technical manuals have been produced and efforts enhanced to promote organizational learning and enhanced service delivery, building on a growing evidence base. The call for evidence with which to inform policy and practice (Banatvala and Zwi 2000) reinforced what was already happening in the field where practitioners and academics were drawing lessons from experiences and enhancing the quality of their responses.

Mortality rates are now much lower than previously seen, malnutrition is declining in many settings, and measles, a major killer in the past, is less catastrophic following efforts to ensure early immunization of children. Enhanced understanding of risks of communicable diseases has decreased risks, although failures to apply evidence, such as in Goma following the Rwandan genocide, still lead to tens of thousands of preventable deaths. Epidemics of some communicable diseases are better controlled and may be less serious and last for shorter periods given improved surveillance and earlier detection of outbreaks. The pattern seen is often similar to the baseline in developing countries, in terms of the major killers. However, the shift has been to seeing many of the highest mortality rates outside of camps, where the public health response has not been as well developed.

Toole and Waldman (1997) describe the need for primary, secondary, and tertiary prevention. In primary prevention, they argue that political and diplomatic mechanisms should be developed to prevent conflicts evolving to the point of mass displacement, and that epidemiology may be able to add value in studying some of the dynamics that indicate conflict developing on a large scale. Secondary prevention comprises early detection of population movements, contingency planning so that relevant actors are prepared for the scale and nature of likely public health crises, having well-trained personnel with knowledge and experience in dealing with the health problems associated with refugee situations and able to rapidly assess and intervene in partnership with local organizations, along with the capacity to monitor and evaluate programmes swiftly and effectively. Tertiary prevention involves channelling resources into combating the sources of morbidity and mortality already outlined. This involves providing shelter and protection, adequate food rations, adequate clean water and sanitation facilities, programmes for preventing specific communicable diseases, preparing for epidemics, specific programmes such as maternal and child health or mental health, managing diarrhoeal disease, and setting up health information systems.

The social, cultural, and political challenges of instituting these levels of prevention, alongside the practical implications of working in such settings, are substantial. Salama et al. (2004) describe how the field has been growing over 30 years, with increasing attention by humanitarian actors since the 1990s to codify technical guidelines. In the early 1990s, there was a growing disappointment and recognition amongst the actors attempting to engage with these complexities, and provide emergency assistance to refugees, that the field was uncoordinated and lacking in technical direction. Research, adverse publicity, and heightened calls for accountability around standards of service delivery and to the supposed beneficiaries of humanitarian interventions, all pointed to the need for significant improvements.

Initiatives were beginning to emerge that were investigating ways to address these issues, but the field was ultimately galvanized by events in 1994 in Goma, Zaire. The unprecedented rapid

influx of refugees and the resulting massive cholera epidemic, producing one of the highest mortality rates recorded, led to a serious reappraisal of humanitarian work in these settings. The Joint Evaluation of Emergency Assistance to Rwanda was an impressive, multiagency, multidonor-funded initiative, paving the way to a deep review of the humanitarian and relief field and the standards of care and conduct.

In terms of future public health directions, Salama et al. (2004) describe the need to move beyond the current refugee and IDP paradigms, as non-camp populations affected by conflict are now often greater in number and burden, and mechanisms to deliver services to such populations are less clear. There is a need for enhanced coverage in all settings of known effective public health interventions, and for the more upstream causes of CEs to be addressed. The technical needs identified include the development of more context-specific methods for assessing mortality rates as an indicator based on surrounding baseline CMRs, and considering which other indicators may point to a deteriorating situation such as fluctuations in disease incidence, levels of displacement, and decreasing food security. They suggest that implementation of control measures should be early, not when mortality and malnutrition are already high, and that whilst communicable disease control should continue to be prioritized along with nutrition and food security, that enhanced efforts at addressing mental health, reproductive health, and neonatal health should also be incorporated. Important policy issues include better means of determining direction and coordination of public health interventions, early identification of a lead agency, and greater effort to support fledgling governments to take the lead with the support of a coherent international system. They suggest that the skills of relief workers should be strengthened and broadened to include knowledge of assessment and prevention of disease, monitoring and evaluation, and international systems, policies, and regulatory bodies.

Ensuring equity in the response and equity in access to services and resources made available remains a considerable and under-emphasized challenge.

Developed countries

In developed countries, the complex political arena and the increasingly restrictive views of host populations towards asylum seekers and refugees complicates the task of addressing the public health of forced migrants. Whilst an array of motivated and effective actors plays a number of different roles in this field, there are few central bodies charged with overseeing the public health of forced migrants as a whole. The policies of the host nations themselves are likely to shape the public health landscape and in situations where these policies seem to be detrimental to the health of this population, public health professionals may find themselves having to take increasingly political roles to fulfil their public health duties.

Advocacy groups and health professional organizations have set up refugee and asylum seeker health networks and centres through which to provide services and support and advocate for more inclusive social and health policies.

The Health of London Project established a health centre in 1999 to provide access to good-quality primary care for forced migrants. The service aims to provide a thorough initial health assessment, along with effective responses to issues such as mental health

problems and communicable diseases. In Europe, Médecins du Monde, an NGO, has stepped in to provide care for groups with restricted access to healthcare, particularly failed asylum seekers.

The best way in which to organize healthcare for resettled refugees, and for asylum seekers, remains contentious. A key issue point of debate is whether they should be integrated within mainstream services, or offered separately through distinct services for these marginalized groups (Finney Lamb and Cunningham 2003). Such centres are often voluntarily run and unable to cover the full extent of need. Hull and Boomla (2006) discuss the implications of such NGO provision, including some of the unanticipated negative aspects.

Another potential theoretical divide that can emerge with health approaches to asylum seekers and refugees is that between public health and human rights frameworks. Governments are more responsive to public health arguments whereby health problems of forced migrant populations may be addressed for the benefit of the wider population, often highlighting the risk brought with incoming refugees and forced migrants of communicable diseases. However, these approaches focus more on protecting the host than the forced migrants' right to receive healthcare (Burnett and Peel 2001) and may reinforce discrimination and marginalization of the migrants who are seen as posing a risk to the general community and demanding excessive use of public services (Grove and Zwi 2006). Tarantola et al. (2008) argue for much closer links between public health, human rights, and development—all equally relevant to forced migration.

Hull and Boomla (2006) describe recent UK government proposals to deny general practitioners the discretion of registering overseas visitors including failed asylum seekers, and to provide care to them. They highlight the possibility that such a policy will inadvertently increase costs through more emergency admissions, and they stress that such a policy is a breach of human rights, ethically unsupportable, and may place clinicians in conflict with their professional duties.

Ashcroft (2005) describes the language of the UK and Australian governments as 'Orwellian' in an overview of their approaches to asylum seekers and health. In discussing the UK government's move to make failed asylum seekers pay for all non-emergency care, despite not having the right to work, he states that the treatment of asylum seekers is an ethical issue and that denial of medical treatment should not be used as a lever to exclude people or get them to leave the country. In some cases, the presence of HIV seropositivity has been used to exclude refugees from the opportunity to resettle in a third country; this is of particular concern given the heightened risk of violence and infection that may characterize the lives of many refugees. Using this against such vulnerable community members is a double victimization.

As Silove et al. (2000b) stated:

the medical profession has a legitimate role in commenting on the general and mental health risks of imposing restrictive and discriminatory measures on asylum seekers, especially when some of these administrative procedures threaten one of the fundamental principles underpinning the practice of medicine: *primum non nocere* [do no harm].

In response to current debates in Australia, the Australian Medical Association issued a position statement on the Health Care of Asylum Seekers and Refugees (Australian Medical Association 2011). This lays out not only the health vulnerabilities of these

populations but also that medical practitioners should insist on the rights of their patients being respected and lays out certain competencies necessary for treating asylum seekers. These include identifying victims of torture, assessing and managing trauma, identifying suicide risk and recognizing health conditions specific to these groups such as TB.

Further study is required to document the patterns of disease, the links to the asylum experience, and impact of policies, not only on forced migrant health but also the implications for host populations are required. Given the more restrictive policy environment, health professionals require a strong evidence base from which to lobby for improved access to services as a first step in improving the health of refugees and asylum seekers in developed countries.

Emerging issues for public health professionals

Many of the issues raised in earlier sections have a technical focus, even if their links with broader sociopolitical issues have been acknowledged. In this concluding section of the chapter, we highlight some of the many issues which challenge professionals and societies, not only on a technical level, but in terms of the values underpinning how we, individually and collectively, whether as citizens or professionals, see and respond to others, especially those who have been forced to flee.

This section seeks to highlight, briefly, a number of key themes: globalization and poverty, quality and accountability, ethics and researching with forced migrants, voice, visibility, and agency. They are central to understanding the context within which forced migration arises and health needs should be understood and addressed.

Globalization and poverty

There is increasing evidence of widening gaps in income and basic needs between the well-off and the impoverished in many settings. Labonte and Schrecker (2005) identify the key links between current patterns of globalization and the influence these have on the social determinants of health. The challenges are evident in the failure to address the Millennium Development Goal (MDG) targets, while extreme wealth continues to be generated and monopolized by small fractions of the world's population. Resource constraints are likely to increase; countries engaging actively with global economic and political opportunities may do well but not all their citizens will necessarily benefit.

Evidence of gaps is widespread; and it is apparent that the MDGs, a major driving force at present in international development, do not adequately address issues of equity (Attaran 2005). Such concerns are likely to be amplified in relation to especially vulnerable and socially excluded communities such as forced migrants, data on whom may be unavailable and systems of response to which will be fragmented, uncoordinated, and inadequately monitored. Colson (2007) argues cogently that much greater emphasis should be placed on understanding the 'factors that provide the impetus to leave' and not focusing only on the aftermath of such forced migrations.

Quality and accountability

A key challenge in engaging with situations of violence, social exclusion, and disempowerment is in ensuring that work

undertaken to assist those affected does no harm, or at least strives to limit the potential harm and maximize the potential value. The international community, through the UN, other multilateral and bilateral agencies, and international NGOs, all ostensibly seek to assist those forced to flee or migrate.

One way in which evidence improvements are underway is in relation to enhancing and seeking to assure the quality of humanitarian and relief work. Major Quality and Accountability initiatives such as SPHERE, the Humanitarian Code of Conduct, the Humanitarian Accountability Partnership, and many others contribute to enhanced practice. There remains a need to facilitate self-reflection and open review, transparency of difficulties, limitations and failures, and promotion and funding for the search to do better.

The vast majority of incentives currently in place, however, encourage the hiding, rather than the declaration, of weaknesses, so as to elicit the next tranche of funding. This is counterproductive when seeking to reflect and improve services and their responsiveness to need. New thinking is required: how do we develop systems of trust and collegiality, mutual support between affected communities, services providers, and agencies, to ensure that all incentives operate to maximize the gain for those at greatest risk?

New initiatives in the humanitarian and relief areas of activity seek to enhance practice and open out debate and public scrutiny. In so doing, weaknesses are identified, guidelines and lessons for better practice formulated, and processes which seek to engage and creatively respond to problems, developed. Taking forward such action requires promoting an ability to report and record limitations and inadequacies, and to carefully and systematically document strengths and limitations, weaknesses and potentials, to address real problems. Services are never ideal and always have constraints and limits; it is crucial to establish ways of examining them such that opportunities to change, to experiment, to creatively engage with solving problems are established.

New and enhanced knowledge management systems would be most valuable if they assisted in finding innovative means of conceptualizing problems, sharing information and insights of what works in different contexts, and developing systems to ensure accountability to the intended beneficiaries, the forced migrants themselves.

Ethics and researching with forced migrants

Ethical issues require considerable attention especially given the power imbalances present and in relation to research. Forced migrants may be especially vulnerable and risk being abused, either through their stories and survival strategies being exposed and used by their opponents to undermine them; the very practice of talking with an outsider or sharing information may heighten risk, vulnerability, and the attention of those seeking further to undermine and disempower. Real risks may result from security lapses, confidentiality lapses, exposure of coping strategies and adaptations; as well as stigma and reinforcement of difference and of 'otherness'.

A major challenge in research with refugees and other forced migrants is to assist them in documenting their experiences of forced migration (Mackenzie et al. 2007). In so doing, the locus of power in the research relationship has the potential to shift from the researcher him or herself, to the communities being researched. The project may shift from research *on* refugees to

research *with* refugees and research *by* refugees for action and change.

While this may be conceptually and morally attractive, the practicalities of achieving this are impeded at multiple levels, not least of which is establishing a trusting relationship between the researcher and the communities with whom they research. Engaging with forced migrants is itself a major challenge: Such communities are often highly dependent on others, and may be reliant on outside agencies with expertise and resources and/or on local power-brokers in control of the basic necessities of life and survival—food, water, shelter, and security.

Zwi et al. (2006) have highlighted the importance of reconceptualizing such research to consider the potential to ensure benefit and reciprocity for the subjects of research and to shift the locus of decision-making in their direction. They offer a model to describe this process, while Mackenzie et al. (2007) present a case study of applying many of these considerations to work with forced migrants on the Thai–Burmese border. Of note is the transfer of power to community organizations, with women's groups from the Thai–Burmese border having control over the stories and narratives collected from them and academics being required to obtain permission from them to publish and distribute and write up such material.

Innovative approaches to research are emerging and warrant support. Youth-focused research highlights the importance of young people in exploring and documenting their own lives and experiences. Young people play a central role in refining and redefining the issues, identifying the challenges and the potential approaches to solving them through new models of participatory action research. Such collaboration needs to build skills, resilience, and opportunities to shape the future.

Voice, visibility, and agency

There is increasing recognition of the importance of hearing from those most affected by any public health condition and ensuring that their voices are heard; empowering them to help shape the proposed solutions. Black (2003) emphasizes the importance of advocacy as a central component of work with marginalized and disempowered groups and reinforces the centrality of ensuring that the voices of those affected, and of the range of stakeholders engaged, is heard.

The voices of forced migrants may be silenced while those of powerful agencies and governments are privileged in shaping our understanding both of the problems and of the solutions which surround forced migration (Harrell-Bond and Voutira 2007). Power imbalances, vulnerability, and cultural and linguistic differences are among the many barriers to creating an environment in which refugees and IDPs are able to take an active part in shaping solutions. As with the youth, truly participatory models of action and research require sensitivity to the challenges of the context and understanding of the conditions that usually deny refugees a voice.

It is crucial that we hear the voices of those most affected by forced migration if we are to recognize the range of experiences, and the positive and negative change and transformation which results. As Eastmond (2007) states eloquently: 'while transformation and change are part of the refugee experience, not all change is perceived as loss or defined as problematic or unwelcome by all individuals involved. Nor are refugees necessarily helpless

victims, but rather likely to be people with agency and voice' (p. 253). Learning and recognizing how agency, transformation, resilience, adaptation and change are shaped, notably, but not only, in relation to gender and power, would not be possible without hearing from and learning with, those most affected.

Conclusion

Forced migrant populations frequently suffer vast health challenges. Their experiences need to be understood within the context of accelerating globalization, with its positive and negative features transforming the lives of millions of people.

The role of public health professionals in working alongside forced migrants to bring about improvements in their health is demanding and complex. A comprehensive understanding of the dynamics of forced migration and sensitivity to the constraints placed on individuals and populations is vital to gain trust and provide opportunities for transforming health outcomes. Particularly, given the increasingly restrictive environments that forced migrants find themselves in, public health professionals can have a crucial role in advocating for forced migrant health, enabling forced migrants to speak and be heard, and to bring about improvements in their own health.

Improving knowledge and understanding is central to affirming the rights and the agency of those affected. Public health can play an important role, and indeed has done so, in improving technical quality of service delivery. Key gaps remain, however, in understanding, appreciating, and responding to the varied ways in which those forced to move seek to shape, transform, and better their own lives and experiences.

Prisons: from punishment to public health

Ernest Drucker

Introduction to prisons: from punishment to public health

The premise of this chapter is that the work of public health should now include consideration of criminal justice systems and incarceration, assessing their specific and changeable effects on population health. Our goal is to determine and measure the outcomes (both intended and unintended) of our varied attempts to use criminal justice systems for public safety and social control. To accomplish this goal we must examine immediate effects and long-term health and social consequences of various forms of punishment, assessing their impacts on individuals and populations both during and after incarceration. This will involve using common public health metrics and methods to determine the collective impacts that systems of criminal justice and their application may play as *social determinants of health* in any society. This work is largely based on the author's experiences and research within the US system—admittedly an extreme case, but one that can serve as a cautionary tale for applying a set of epidemiological principles to the data of criminal justice to demonstrate just how consequential criminal justice policies can be for a nation's public health. This chapter uses epidemiological principles and data to create a basic template—a framework for the public health analysis of imprisonment. It considers the consequences of incarceration for individual inmates, their families, communities, and societies at large. As a first such attempt, it is necessarily a thin slice of a vast body of material and concepts about both prisons and public health, but my hope is that it still may serve as a useful primer and a map for future explorations.

The appearance of a chapter on prisons in a public health textbook is a landmark in the development of our contemporary appreciation of the actual and potential significance of both crime and its punishment in human affairs. The rationale and conceptual framework for examining modern criminal justice systems as a public health phenomenon are a consequence of the large scale and potency of state systems of punishment. As these grow in size and importance, they play an increasingly significant role in determining the health of entire populations. In this chapter, I examine the basis of these systems' functioning and the forms and levels of the punishment they mete out—viewed as health determinants. While my own experience and much of my understanding of these relationships derives from US data, my aim here is to provide a template for public health analysis of other societies

and their contemporary systems of criminal justice. I will interrogate the stated intentions and document the concrete behaviours of these systems and their demonstrable outcomes affecting individual and collective health outcomes.

Viewing these systems through a public health lens provides us with some new models for gauging their significance and expands the assessment of their many impacts that extend beyond the administration of criminal justice, including effects upon population morbidity, mortality, social justice, family and community health, and human rights. In examining the public health consequences of criminal justice methods and their application to specific populations, we are drawn first to the examples of the large-scale use of incarceration as punishment (*mass* or *hyper-incarceration*) and the range of important health and social consequences that occur as a function of its large scale and concentration of the use of imprisonment, that is, its 'dosage effects' upon populations (Drucker 2013).

Prisons have many health effects—upon morbidity, mortality, and the life course of individual prisoners and upon their children—suggesting an intergenerational impact. International imprisonment data, employing uniform measures that allow clear comparisons of the prevalence and population characteristics of imprisonment worldwide, are still often incomplete or unreliable. Even so, these data do enable us to make basic comparisons and link the data to public health. This is most evident for the developed nations—especially the United States, the nation with the largest number of prisoners and the highest rate of imprisonment in the world—whose data density makes it a case study of mass incarceration and of the wealth of data that are possible to study (Christie 1997).

Another major goal of this analysis is methodological—to demonstrate how well criminal justice data lends itself to the methods of public health analyses, to observe important patterns of contemporary population health issues (such as HIV and addiction), and to see evidence of incarceration as a contemporary driver of population health. Using a 'public health lens' (Drucker 2013) to examine criminal justice and incarceration provides a much-needed model to approach this important but often overlooked determinant of population health. It includes a model of prevention, the scientific methodologies needed to identify risk and protective factors, as well demonstrating the value of multidisciplinary collaboration characteristic of all effective public health interventions. Other chapters in this text cover some of the

same territory (e.g. drugs, violence, mental health) under different rubrics, but my hope is that this exposition will allow the public health professional and student to see the scope and location of many of the field's most important features relative to public health and encourage their own further exploration.

Prisons and society

What is there to say about prisons as discussed here for the first time in a venerable textbook of public health? First off, while medicine and public health are themselves certainly also venerable, crime and punishment are even more so. The trope of crime and punishment, established early in human history, is arguably a foundational constant of human social development and the organization of the modern state. Differences in systems of governance based on the *rule of law* are a defining characteristic of most organized societies. But so is the frequent transgression of these rules and, with that basic fact, the need to address these violations—the criminology of everyday life. If the social contract is about anything it is about meshing individuals to the contours of their social order—and that order is ultimately defined by its rules and restrictions—including the responses to their violation, as much as by their benefits and opportunities.

Historically most of the theory, scholarship, and research about criminal justice systems and the populations they affect most directly (offenders and their victims), have drawn their core conceptions and research questions from the fields of criminal law and sociology/criminology. The social sciences have traditionally concerned themselves with prisons as the social and political end points of crime and its punishment (Garland 1991; Morris and Rothman 1995). These fields appropriately emphasize the objectives and methods of crime control, that is, their desired impacts on public safety, while examining the characteristics and behaviours of the affected populations (both criminals and victims) and the workings of the systems of enforcement that accompany them.

The framework of criminal justice theories and policies have focused on response to transgressions and attitudes towards deviance: including the importance of social order (Durkheim), the structural aspects of social justice and the inequities of class (Marx), and the exercise of state power and its attempts to use criminal justice systems to exert political control over individual and group behaviour (Foucault).

This body of thought constitutes the conceptual foundation and basis of the legal structures and practices of criminal justice. These criminal justice concepts and models concern themselves with core societal issues, for example, assuring social order, supporting the conditions for secure and peaceful communities, protection of family life, providing safety from violence, and providing for the administration of justice under law. These experiences and the data they yield have heretofore (understandably) been almost entirely discussed in terms of their success or failure in the establishment and maintenance of law and order—with a focus on public safety and crime control. In this public health analysis of criminal justice systems and their consequences we take a different perspective—examining the full range of effects of the workings of criminal justice systems—not just effect on crime but on the overall health and well-being of entire populations, which includes, but is by no means limited to, crime and its victims.

Criminal justice systems apply punishment to individuals in response to real or perceived offences against other individuals and the common good. But it is *punishment itself*, not just the formal rules under which it operates, that is the essential variable for public health. Both for individuals and in the aggregate, it is the forms and severity of punishment that are the measurable exposures that drive the public health impact of imprisonment. The human experience and responses to punishment form the basis of any therapeutic or pathogenic agency that the criminal justice system may have. Nils Christie, the great Norwegian criminologist, has put it very clearly: ‘punishment is pain’ and ‘imposing punishment within the institution of law means the inflicting of pain, intended as pain’ (Christie 1981).

Punishment by incarceration involves extended suffering and deprivation of freedom (perhaps the greatest pain of all), administered for the reasons of exercising control. But this pain has a wider audience than the offender and many collateral consequences, among them it has the added purpose of deterring others, who may learn from the example and desist from transgressing. In public health terms, the consequences of punishment depend on the scale and methods of its application in practice. All systems of law enforcement expose the offender to life-altering effects—ranging in severity from disapproval and stigma, to often brutal and humiliating treatment, long periods (up to a lifetime) of misery in prison, or (in the ultimate punishment) to loss of life itself, by execution. In the forms and levels of punishment that each society metes out, we may see ample evidence of its limitations. Increasingly these include the inevitability of significant collateral consequences on populations other than the offender, particularly their families, which also defines the system's larger impacts on society, and its powerful tendencies and abilities to replicate and sustain itself.

Individual and population data

Just as individual cases are the foundations of clinical medicine (upon which public health is built), it is the individual cases of ‘crime and punishment’ that form the data of the criminological sciences. This primacy of the individual case in law (as in clinical medicine) has great historical power and authority, framed as it is in deeply rooted (and wholly understandable) moral precepts of ethics and justice, right and wrong, and the conditions of each individual's implicit and explicit social contracts with authorities and government—where we routinely sacrifice some of our autonomy (individual freedom) in exchange for the many benefits of organized society and the fundamental protection of those rights—for example, of our property and personal safety, as well as protection of the weak from the strong.

The aggregation of individual case data (on both crimes and punishment) comprises the units of analysis in analytic criminology and jurisprudence, these aggregations are only a summary of the individual cases—as much an expression of the system's ever changing definitions and rules as determined by each society's systems of making and enforcing laws in practice, and played out as criminal justice procedures and outcomes. While many crimes are violations of ‘natural law’ (e.g. violence, theft), criminal offences are determined by legal statutes, and laws always subject to change, sometimes arbitrarily so.

The legal doctrines that govern criminal justice theory and practice demonstrate that the *individual case* is the core unit of analysis, and the target of intervention. In clinical medicine, the individual case is also the basis of practice, but public health data and clinical epidemiology are recognized as the key to understanding the overall impact and burden of disease, in the distribution and determinants of population health. Similarly, while the aggregate data of criminology are essential for shaping beliefs, expectations, and the many questions that occupy criminal justice theory and scholarship, the actual models of legal practice in courts of law, steadfastly remain based solely on the individual case and its precedents.

However, the ‘case definition’ of a particular instance of criminal offence may not be as rigorously defined as we are accustomed to in medicine and public health. The categorization of criminal acts as criminal justice data are ultimately determined by very subjective criteria—the interpretations of legal statutes by the police, prosecutors, judges, and juries—always negotiable in legal practice and adjudication. This inherent vagueness of criminal justice cases sets limits on their reliable use in scientific analysis. Aggregate or population research (which might be used to validate case data) is generally *not* admissible as evidence in criminal court cases, except for forensic findings of fact, used as evidence in the determination of guilt or innocence on a case-by-case basis. Such variability in legal case definitions still leaves us with individual criminal cases as the basic unit of analysis, both for practice and for the scientific analysis of crime and punishment data—compromising our ability to ascertain clear and replicable findings of complex relationships that determine population health outcomes.

But, while *individual* crime and its punishment may be the foundational unit of all theories and practices of criminal justice and its enforcement systems (Garland and Duff 1994), the public health lens allows us to step back and recognize the wider social and population significance of the individual circumstances of punishment and the workings of our criminal justice system itself. We therefore seek near universal or paradigmatic models of the relationships between individuals with their governments and each other (i.e. the social contract). In public health we are challenged to see criminal justice systems anew, as an important factor in the larger framework for any population’s health and well-being. We are therefore obliged to undertake the task of assessing the health and social consequences of our systems of criminal justice as a determinant of population health—an obligation that feeds back to the accountabilities of any system of governance for all of the diverse, often damaging, collective consequences of its actions—and not just the simple sum of an array of individual criminal acts and their punishment. Despite these limitations we may still understand criminal justice phenomena in public health terms—one of the many systems in complex modern societies that makes substantial contributions (for better or worse) to the general health and well-being of the people. More specifically, we may examine the relationship of different systems of criminal justice and their methods of punishment to the population’s health.

Prisons and public health: the epidemiology of punishment

Systems of criminal justice and the modes and levels of punishment meted out are a defining feature of different societies. We

are now learning that these may affect population health in many ways—first off (as in all epidemics) by their scale. As our systems of criminal justice and the uses of incarceration reach new levels (with over 9 million prisoners worldwide and growing (Walmsley 2012)), we must learn to better understand the nature and significance of these systems and the collective consequences of their common modes and levels of punishment and examine evidence of their effects on populations. We start with the fundamentals of epidemiology—prevalence and incidence levels and trends; patterns of risk by time, place, and person; and models of primary, secondary, and tertiary prevention.

The prevalence of imprisonment at the national level worldwide, ranges by a full order of magnitude from less than 50 to over 700 per 100,000 population (Fig. 10.10.1). The application of such dramatically different rates of punishment by imprisonment is the first metric of its public health significance. With this understanding of the reality and significance of such wide variations in the magnitude and methods of punishment by imprisonment between societies, we may embark upon a closer examination of their specific consequences and population impacts. And we must remain mindful of the fact that any system of punishment, has powerful influences on the larger population beyond the individual offender—effects that may extend far beyond the individual cases of crime and its punishment which are its intended targets.

Criminal justice systems as a determinant of health

As we consider the public health significance of our systems of crime and punishment we are drawn to the special role of imprisonment and its effects on health outcomes for prisoners and others close to them. To accomplish this goal we must examine criminal justice systems closely—using the traditional epidemiological tools, metrics, and analytic methods and models of public health (i.e. morbidity and mortality; the traditional statistical analysis of population health data by risk factors and population variables). We wish to fully understand the health outcomes of particular methods employed in systems of punishment, and the consequences of that system for population health.

As systems of criminal justice grow in scale globally, they are emerging as a new form of social influence that emulates the role of the many other biological risks and social pathogens to which we are all ‘exposed’—such as environmental factors (pollution and effects of climate change), poverty, inequality and social injustice, violence, and wars. And, just as we consider the effects of the application of various modes of punishment to individuals who transgress laws as a means of crime control (i.e. imprisonment as incapacitation of offenders by their temporary removal from society and as a deterrent for others) we are now realizing that the effects of widespread punishment are already evident in many nations (Waquant 2009), and thus may already be appreciated as significant determinants of public health when applied to an entire society—particularly as *hyper-incarceration* or *mass incarceration* of particular racial or ethnic groups.

Just as the rule of law reflects the political and social realities of its time and place in any society, we must now also be aware of how these systems can impact public health. Amidst the many other developments of a rapidly changing world we are now beginning to understand the important role of international crime and corruption as phenomena that have powerful effects on *global health*, for example, the illicit drug trade, human trafficking, civil wars, child

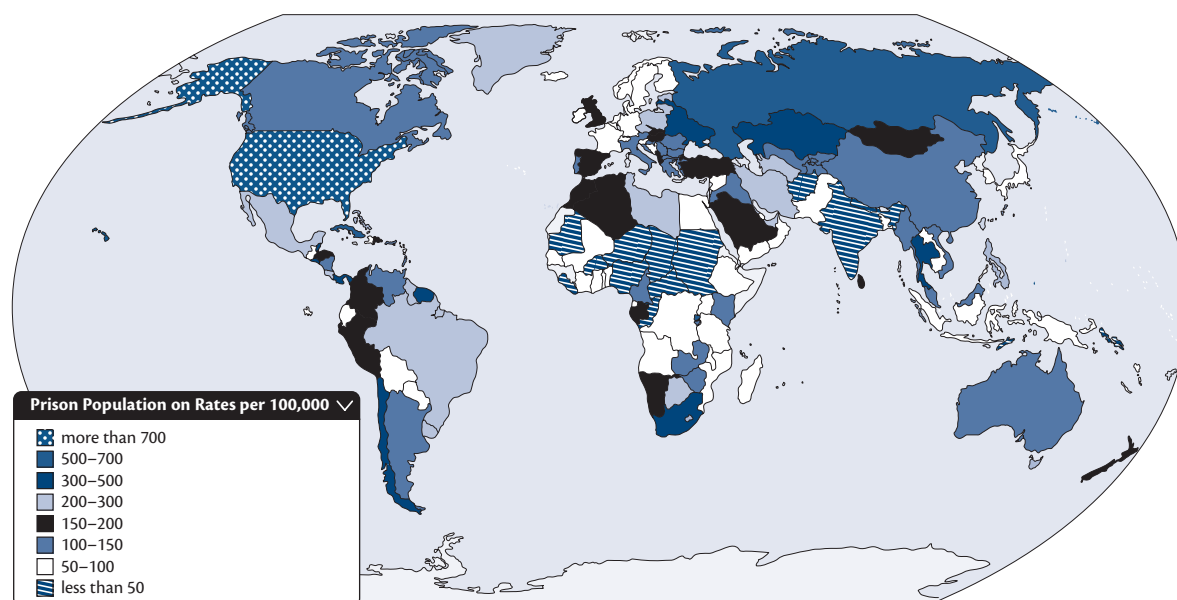

Fig. 10.10.1 Global rates of imprisonment.

soldiers, terrorism, as well as many environmental risks where violations of protective laws endanger and degrade the atmosphere, the seas, and the fertile landscape on which we all depend. In these ways the successes and failures of our attempts at crime control emerge as one of the most potent new determinants of population health and the prosperity and social welfare of nations.

Effects of incarceration on crime

The impact that imprisonment has upon individuals typically focuses on its role in controlling crime, not on its health consequences for offenders and their families—although crime reduction (certainly the prevention of violent crime) can be seen as a positive population health effect of incarceration. The conventional wisdom in criminology is that incarceration controls crime in two ways: deterrence and incapacitation. For deterrence it is held that the example of the punishment of offenders builds the fear of punishment into others who might be caught committing a crime. The other intended role of imprisonment in crime prevention is through ‘incapacitation’, that is, removing the individual from society for some length of time limits his or her ability to commit new crimes while behind bars.

The literature of criminology is full of studies debating the effectiveness of incarceration as a deterrent (something that is very difficult to prove or disprove), but there is a general consensus about the role of incarceration in incapacitation—imprisonments clearly does limit the harms that any individual might do while free. By this logic, the greater the number of criminals who are incarcerated the more crime is prevented overall—at the very least by the incapacitation effect. This is a common claim used to support high imprisonment rates and long sentences (without parole) as a guarantor of public safety. These arguments have intuitive appeal, but the data on the incapacitation effects of mass incarceration are often equivocal (Drago et al. 2009), in part because so many other factors determine the variations in crime rates in any

society. In addition, of course, the vast majority of prison inmates have not committed a violent crime.

Yet the notion persists that by taking criminals off the street, imprisonment prevents them from committing new crimes, an idea that remains a cornerstone of the justification for high rates of imprisonment. Getting the ‘bad guys off the street’ has a pragmatic intuitive appeal, aside from satisfying some more retributive impulses. What these criminological models do not generally acknowledge, however, are the long-term adverse individual health and social consequences of incarceration itself—that is, the effects of systematic punishment on human beings. This is where a public health model can be most useful.

Both acute and chronic problems are important effects of exposure to the systematic punishments that are routinely associated with incarceration—that is, the many daily humiliations, experiences of personal helplessness in the face of the arbitrary exercise of power (often sadistic) by the prison authorities, brutality and cruel treatment by other prisoners and guards, and significant dangers of traumatizing personal assaults—including sexual assault by both other inmates and guards. Attempts to prevent such cruelty and violence in prisons runs throughout their history—and is the subject of the efforts of many national and international organizations struggling to establish and enforce standards that assure humane prison conditions (van Zyl Smit and Snacken 2009) and to promote the fair and humane treatment of all incarcerated persons in detention and prisons, meeting contemporary ethical, legal, and human rights standards (John Howard of London and District n.d.).

The prisons revolving door: re-entry and recidivism

Most of those who are incarcerated are only ‘incapacitated’ temporarily, and most return to the communities from which they came—albeit the worse for the experience (Travis 2005). Recidivism (readmission to prison) due to new offences or

failures to meet the conditions of parole (e.g. relapse to drug use) is taken as a failure of the rehabilitation potential associated with arrest and imprisonment. An analysis of US recidivism patterns of 40,000 offenders released from state prisons in 1994, discovered that 56.2 per cent resumed their pre-incarceration offending trajectories after release, with no apparent effect of imprisonment on future risk of re-incarceration (Loughran et al. 2009; see also Pathways to Desistance 2014), controlling for age and other characteristics. Another meta-analysis (Cullen et al. 2011) concluded that the absolute impact of incarceration is, 'at best, marginal and at worst, iatrogenic' in predicting recidivism. In a series of studies, Clear and Rose and others (Clear 1996, 2009; Rose and Clear 1998; Fagan et al. 2003) have found that higher rates of arrest and incarceration in a community often lead to higher community rates of incarceration. In sum, most studies have found either no change or decreased rates of recidivism associated with shorter sentences or early release, while also finding little effect of increases in 'dosage' (sentence length) on a wide array of offenders.

Aside from these studies of prevalence, there is an important body of research by Belfast criminologist Shadd Maruna (2011) that examines re-entry as an opportunity to stop the recurrent cycles of recidivism by addressing it with the same degree of seriousness and formal institutions (even rituals) that accompanies one's entrance into the criminal justice system in the first place (e.g. re-entry courts aimed at reducing recidivism through specific structures and procedures that are instituted with all the thoughtfulness and ritual that accompanies the process of accusation of a crime, adjudication, and sentencing leading up to admissions to prison).

Morbidity and mortality

The rates of mortality in prison populations include all the usual causes of death seen in comparable populations. But the incidence and prevalence of mortality data also reflect the selective nature of prison and jail populations and reflect these environments and their unique risks—and (in some cases) protections, for example, higher rates of suicides but lower rates of homicide in prisons and jails, with important differences to be seen between jails (short-term detention facilities) and prisons—where inmates may spend the rest of their natural lives growing old behind prison bars (Fellner 2012; Williams et al. 2012). See Table 10.10.1.

Prevalence

The current US prison rate of 720 per 100,000 members of the population is both the highest rate and greatest number of prisoners of any nation in the world: with 5 per cent of the world's population, the United States now accounts for 25 per cent of the world's prisoners. If this population of current and former prisoners inhabited their own city, it would be the largest in America. The US prison system now represents the extreme of epidemic incarceration—between 1975 and 2010 about 10 million Americans were in state and federal prisons and local jails.

The significance of prevalence measures of incarceration

Incarceration systematically damages key elements of the psychological and physical health of prison inmates, causing or exacerbating conditions including addiction, mental illness, and chronic infectious or metabolic diseases. Restrictions placed on ex-felons

Table 10.10.1 Mortality rate per 100,000 US state prisoners, by cause of death, 2001–2009

Cause of death	2001	2002	2003	2004	2005	2006	2007 ^a	2008	2009

Note: data are from the *Prisoners at Midyear* series. Data may have been revised from previously published statistics to reflect updated information. State prison mortality rates are per 100,000 inmates held in state custody (including private facilities) on 30 June of each year. The mortality rates presented are not adjusted for age sex, race, geographic location, or any other characteristic. Executions are not included; for data on executions, see *Capital Punishment, 2009 – Statistical Tables*.

^a In 2007, a high number of cases were missing cause of death information. These cases were classified as all other illnesses.

^b Includes other specified (such as cerebrovascular disease, influenza, cirrhosis, and other non-leading natural causes of death) as well as unspecified illnesses. See *Methodology* for details on illness classifications.

after they have left prison extend many of the elements of punishment that occur within prisons—including restrictions on access to employment, decent housing, public benefits for education, and civic participation (voting), as well as the stigma of being an ex-felon, which disables their ability to function effectively in the outside world, incapacitating their attempts to regain a foothold in noncriminal life and to re-establish a place in their families and home communities, for example, in Russia every prisoner has a large red stamp in their passport. These serve to extend the damages of a prison sentence to ‘life on the outside’ (Gonnerman 2004).

Potential years of life lost and DALYs associated with imprisonment for drug offences in the United States: 1975–2010

Assessing the relative significance of incarceration for population health can usefully employ the public health measures of potential years of life lost (PYLLs) and disability-adjusted life years (DALYs). With large-scale systems of incarceration, such as the US one, the years of life ‘lost’ to imprisonment are now comparable to those for many diseases, world wars, and very large-scale natural disasters. Over the last 35 years, the United States has incarcerated 8–10 million individuals, mostly young adult males in the age range 18–34, often for drug offences during the stages of its most rapid growth. The result of incarcerating this many young men can be understood as representing a minimum of 14 million PYLLs. Given the average lifespan of this population, 14 million PYLLs translates to 350,000 deaths in a population of a similar age—more than the number of US soldiers killed in combat in the Second World War (Drucker 2002).

Disabilities imposed by time spent within prisons

None of the rationales for imprisonment (in the United States or most democracies) includes the concept that this form of punishment should cause long-term hardship or permanent harm to individuals and their families. While some societies still defend the most lurid responses to crimes (including flogging, amputations, stoning, and executions), most developed Western democracies show a long and clear trend away from those sorts of punishments. In developed nations (formerly including the United States) there has been a steady movement since the Second World War towards better prison conditions, shorter prison sentences, and more genuine and effective efforts at rehabilitation.

In part this has come about as a result of recognition of the eventual re-entry of most prisoners into the communities from which they came. In the United States, of the 700,000 prisoners who now leave prison each year, over 60 per cent return directly to their home communities. Most are seeking to re-establish the family and social ties that constitute their only social capital—the networks of support so necessary to the prospect of their resuming normal lives. But most do not stay outside very long: recidivism is massive, with about one-third of released prisoners rearrested within the first 12 months, and two-thirds of released prisoners returning within 3 years. This is the most powerful factor that now defines incarceration as a chronic condition—the ‘revolving prison door’ that has become the hallmark of America’s brand of mass incarceration.

In addition to PYLLs, the impact of incarceration can also be measured by DALYs—defined by the World Health Organization

(n.d.) as ‘the sum of years of productive life lost due to disability’—DALYs represent the ‘burden of disease’. While one effect of incapacitation is to prevent continued criminal behaviour while incarcerated, prison also incapacitates these individuals in quite another way, that is, by making them far less capable of returning to a productive life on the outside once their prison term ends. For the United States as a whole (in 2004), there were 12,844 DALYs per 100,000 general population. At any time about 13 per cent of the nation’s population was disabled due to the usual problems of illness, disabling injuries, and ageing. Of the 700,000 individuals released from US prisons in 2009, about 30 per cent were sufficiently ‘disabled’ to fail at re-entry and be incarcerated in the first year after their release, yielding a DALY rate of 30,000 per 100,000 (or 30 per cent). Thus the DALY figure in the first year after release from incarceration is more than double that due to all other disabilities in the general population.

Incarceration as a population exposure

The consequences of involvement with the criminal justice system can now be viewed as we would the long-term effects of *toxic exposure to punishment*. The US data for lifetime risks of imprisonment (Table 10.10.2) clearly show the wide disparities in this exposure by race and its powerful association with educational attainment—a marker for future economic and social outcomes (such as marriage) and for life expectancy itself.

The graphic representation of these same data (Fig. 10.10.2) illustrates the exposure history of the entire US population to imprisonment—showing a tripling over successive birth cohorts.

While a primary intent of incarceration is to punish (by depriving the prisoner of the benefits of freedom for a finite period of time), the long-term effects of incarceration on physical and mental health extend punishment far beyond the period of the sentence itself. Viewed in these terms, incarceration imposes a substantial ‘burden of disease’ for individuals and populations of prisoners.

Table 10.10.2 Lifetime imprisonment rates for US birth cohorts by race and age

Risk of imprisonment by age 30–34: men born 1945–1949, 1970–1974		
	Born 1945–1949 (%)	Born 1970–1974 (%)
All white men	1.2	2.8
All non-college	1.8	5.1
High school dropout	4.2	14.8
High school only	0.7	3.8
Some college	0.7	0.9
All black men	9.0	22.8
All non-college	12.1	30.9
High school dropout	14.7	62.5
High school only	10.2	20.3
Some college	4.9	8.5

Fig. 10.10.2 Percentage of adults ever incarcerated in state or federal prison, by year of birth and age.

Source: data from Bonczar, T.P. and Beck, A.J., *Lifetime Likelihood of Going to State or Federal Prison*, Bureau of Justice Statistics Special Report, US Department of Justice, Office of Justice Programs, 1997, available from <http://www.bjs.gov/index.cfm?ty=pbdetail&iid=1042>.

It is difficult to reconcile these data with the basic rights granted by democratic constitutions and human rights standards. Yet in the United States every year, hundreds of thousands of prisoners become afflicted with physical and mental diseases in prison that do not go away at the end of their sentences, and have their lives disabled by the punitive ways our society treats ex-felons.

The conditions within prisons have powerful effects, many of which stay with the individual for life. The adverse effects of incarceration on individual prisoners include the ongoing consequences of poor healthcare services in prisons; failure of prison security to provide a safe environment (the ensuing rape, violence, and gang activity that have become a routine part of prison life); serious and persistent mental health problems and inadequate mental healthcare in prisons; and a paucity of addiction treatment and the absence of effective drug rehabilitation. All this is in addition to the immediate and longer-term psychological implications of trauma associated with overcrowding, poor prison conditions, and many severe disciplinary methods, including isolation and solitary confinement.

Individual healthcare and imprisonment: a sentinel population for vulnerability

The populations of prisons are an important sentinel population of the most vulnerable sectors of any society. A former Medical Director of Corrections in New York State, calls prisons ‘a window on our society’ arguing that inmates are ‘public health sentinels’ for the most vulnerable populations suffering from all the physical and mental illnesses, communicable diseases, and consequences of alcohol and substance abuse (Greifinger 2002, 2005). Greifinger also notes that the morbidity of American prisoners is higher than virtually any other group (Glaser and Greifinger 1993) for diabetes, asthma, hypertension, and heart disease. In the United Kingdom, recent disclosures reveal that poor food, bad healthcare, and stress are responsible for many deaths in British prisons—with

‘self-inflicted’ causes accounting for more than half of all deaths over the last decade (Thompson 2010). Deaths in custody (including community corrections) are increasing: ‘almost 230 people died in prison or other forms of custody in England and Wales during 2011–12’, representing a 15 per cent rise on the previous year (Anonymous 2012; Prisons and Probation Ombudsman for England and Wales 2013; Inquests n.d.).

There are many serious health problems already prevalent among the populations most likely to be incarcerated—they do not begin with arrest and imprisonment. Overwhelmingly, prisoners in most countries come from the poor communities—often immigrants or ethnic and racial minorities. Their ills in prison faithfully mirror those that these same populations suffer at home—where they have generally gone untreated, for example, mental illness, drug addiction and alcoholism, infectious diseases—especially sexually transmitted diseases (STDs)—viral hepatitis, and HIV/AIDS are at very high levels in this population and demand significant care in prison as well.

Many of the chronic illnesses seen in prisoners—addiction, mental illnesses, diabetes, hypertension, asthma, heart disease—were poorly controlled at the time of admission to the prison system as a result of poverty and long histories of poor access to healthcare. In some cases, such as those involving court-ordered care for prisoners with HIV/AIDS, for example, prisoners may receive better medical care in prison than they would receive outside. But the norm is inadequate healthcare for the incarcerated. This tends to worsen the pre-existing condition, especially in the case of addiction and mental illness, which figure so prominently in the reasons for arrest and incarceration in the first place.

More than 80 per cent of US prison inmates enter prison with histories of, or current, problems with drug abuse or dependency, and drug use often continues throughout prison stays—typically at lower levels, but often with more dangerous practices associated with clandestine injecting via unsterile needles and syringes shared by many inmates. Drug users are generally distrusted when it comes to receiving routine medical care (both in prisons and outside), with many medical providers discounting their demands for pain medications—even in cases involving bone fractures.

Healthcare services are a constant flash point for correctional institutions in America and elsewhere. A study of New York State prison health services found that medical care complaints represented the most frequent inmate grievance—about 20 per cent of all complaints filed by inmates (Correctional Association of New York 2009).

These medical grievances include:

- ♦ Denials of and delays in access to healthcare.
 - ♦ Inadequate examinations by nurses and physicians.
 - ♦ Failures to treat chronic medical problems expeditiously.
 - ♦ Delays in access to specialists and inadequate follow-up by prison providers on specialists’ recommendations.
 - ♦ Problems with receiving medications and the health education needed to comply with complex medication regimens.
- (Correctional Association of New York 2009)

In addition to the neglect of pre-existing medical conditions and major lapses in consistent medical care, the deprivations and stresses of prison life and the poor quality of prison diet increase the severity of chronic diseases. Ironically, imprisonment is often the occasion for these individuals to receive medical care for the first time. In the United States, prisoners are the only civilian

population with a 'right to healthcare' under the US Constitution's Eighth Amendment, which bars 'cruel and unusual punishment', leading to legal support for prisoners' unique entitlement to decent medical care in America. But, despite frequent court mandates to provide this care, extremely poor inmate health services persist in many of the nation's prison systems. This is also true of the continuity of care in prisons and aftercare upon release. Adult inmates are regularly transferred from one prison to another, with disruptive effects on any healthcare that they do get. Prisoners often assert (and a recent New York study confirms) that they are not promptly seen and evaluated when transferred to a new facility. Records often fail to follow them in a timely fashion. Many inmates being discharged from custody leave without adequate documentation of their medical status and without appropriate medication or a medical discharge plan. In the United States there are new plans for extending access to healthcare for prisoners after release under the terms of the Affordable Care Act (ACA), going into effect in 2014 (Phillips 2013).

Increased potential for contracting an infectious disease such as AIDS, hepatitis, tuberculosis, or a STD is another feature of prison life. Inmates face a heightened risk of acquiring blood-borne infectious diseases, due in large part to the sharing of contraband drug-injecting equipment with others in prison. The risk of acquiring STDs is increased through consensual but unprotected sex, and by rape in prison. In the United States an estimated 60,500 inmates—4.5 per cent of the nation's prisoners—report experiencing sexual violence ranging from unwanted touching to non-consensual sex, according to a recent Bureau of Justice Statistics survey of federal and state inmates (Mazza 2012). Yet few inmates see any point in seeking the protection of prison authorities; a separate Bureau of Justice Statistics survey found that only about 6500 official allegations of prison sexual violence (by staff or inmates) were reported to correctional officials in 2006—about 11 per cent of the cases. The report found a number of methodological problems that are common to studies of sex offences in prisons: that is, low response rates from victims due to embarrassment or fear of reprisal, difficulties verifying victims' self-reports, and the lack of common terms to describe sexual abuse (Mazza 2012). Recent reports of sexual offences by staff in juvenile detention centres in the United States have launched a new federal investigation of sexual violence faced by close to 3 million juveniles arrested each year (Travis 2009).

Ageing prison populations

Another effect of mass incarceration and longer sentences is that prison inmates are now an ageing population. According to the most recent report of the Bureau of Justice Statistics (2010), 4.3 per cent of all inmates in the United States in state or federal prisons were over the age of 55 as of mid-year 2008, compared with 3.5 per cent at mid-year 2004, a 23 per cent increase. It costs \$70,000 per year to house older prisoners, two to three times the cost of housing younger prisoners. This situation will only worsen in the years to come as longer sentences intersect with shorter life expectancies. As previously noted, many of today's prison inmates will die in prison because their sentences exceed their life expectancies. Of the 5200 men at Louisiana's infamous Angola penitentiary, an 18,000-acre former plantation, journalist Mary Foster estimates that approximately 90 per cent of inmates will die in prison, due to the length of their sentences. These health issues collectively mean

that, even for those who enter prison young and healthy, a prison sentence is tantamount to being afflicted with a chronic illness or long-term disability. The deplorable state of prison healthcare is one of the prime reasons a prison term leads to a lifetime of full or partial incapacitation, transforming a finite sentence of incarceration into a lifelong disabling condition.

Drugs, addiction, and their treatment in prisons

Significant problems with drug use and alcoholism are ubiquitous in US prisons (Mumola and Karberg 2006). US studies estimate that 60–83 per cent of the nation's correctional population has used drugs at some point in their lives, twice the estimated drug use of the total US population (40 per cent) (Fellner 2012). Drug offenders accounted for 21 per cent of the US state prison population in 1998 (up from 6 per cent in 1980), 59 per cent of the federal prison population in 1998 (up from 25 per cent in 1980), and 26 per cent of all jail inmates, mirroring the steady increase in arrests for drug offences over this period. Women in US prisons were more likely than men to report using drugs in the month before their offence (62 vs. 56 per cent) and were also more likely than male inmates to have committed their offence under the influence of drugs or while engaging in petty theft or prostitution to get cash for drugs.

A programme recently instituted in Baltimore, Maryland, United States, provided methadone maintenance for prisoners who were soon to be transferred to community-based methadone programmes at release. These prisoners had significantly better outcomes than a control population provided with only 'counseling and passive referral' after discharge. Results included more time spent in treatment during the 12-month post-release period, and far fewer positive urine tests for heroin and cocaine (Prisons and Probation Ombudsman for England and Wales 2013). But because of hostility towards the use of methadone in correctional settings in the United States (it is also barred in almost all drug courts), such programmes are rare.

Accordingly, the first thing many released prisoners do on getting out is seek relief by injecting heroin—often with lethal results. Over 25 per cent of drug fatalities due to overdose are now thought to stem from this phenomenon. The failure to address addictions in the criminal justice system is the single most significant reason for re-arrest and recidivism once released. This amounts to a systemic failure that diminishes each individual's chances of successful re-entry at the end of a prison term. Instead, re-entry becomes associated with a resumption of drug use that, while not altogether absent, had been greatly reduced during imprisonment. But this is a clear case of incarceration heightening a disabling condition with lethal effects on the outside.

Internationally many other countries now also have large proportions of drug users in prison, but many now also offer a wide range of treatments (including methadone) to incarcerated drug users (United Nations Office on Drugs and Crime 2013). Many also have employed harm reduction strategies to reduce HIV and hepatitis C virus transmission in prisons (e.g. methadone substitution treatment and access to clean injecting equipment) and now also seek to avoid imprisonment for those with addictions (Dolan et al. 1996, 2003).

Most US prisons have been resistant to this approach. While there are many very dedicated peer drug counsellors in prisons, their efforts to rebuild self-esteem and equip inmates to deal with

the dependency and high risk of relapse are thwarted in these anti-therapeutic environments dominated by punishment. There is little incentive to offer effective drug treatment in modern American prisons—a neglect framed as part of the prison ideology in which inmates must assume ‘personal responsibility’ for their present circumstances. Building on this seemingly reasonable conception, most drug treatment in prisons is moralistic in tone, depicting addiction as evidence of personal weakness (confirmed by the great personal failure that incarceration has come to represent) and often seen by inmates themselves as ample justification for their current punishment.

In consequence, the way the United States treats drug addiction in prison has become an extension of the moral crusades of America’s war on drugs—where legitimate questions of how best to minimize the harm from drugs are subordinated to the goals of zero tolerance—even for therapeutic drugs that soften the pains of withdrawal. Drug problems of prisoners have now become the basis of a virulent ideology of condemnation and demonization, undermining any personal strengths they may bring with them into prison and creating further, lifelong problems for inmates—problems that may result in their rapid return to drug use after release.

Evidence for this failure can be seen in the high rates of drug overdose that occur in the period immediately following discharge of drug users from prisons. Multiple studies have confirmed that overdose deaths among people who used heroin prior to incarceration are increased tenfold in the 2 weeks after release from prison, as compared to the usual overdose rate (Binswanger et al. 2007).

This result has been seen in the United Kingdom, Canada, and Australia, which all have drug problems similar to that in the United States but incarceration rates of drug users that are only about one-quarter of US rates. Opiate overdoses are thought to be due to the loss of tolerance associated with the greatly reduced use of opiates in prison. In the United States, the most significant reason for this can be found in the failure to treat opiate dependency adequately in prisons. More specifically, it can be attributed to the failure to allow known opiate-dependent individuals to use methadone in prisons. When there *is* drug treatment (consisting mostly of prisoners talking in groups), the most common philosophy is modelled after the drug-free therapeutic communities that philosophically dominate American drug treatment—generally to the exclusion of approaches that employ medications such as methadone or buprenorphine, known to be the most effective methods available to treat opiate addiction.

The high rate of drug incarcerations ensures that drug problems will be very common in prison populations worldwide. In the United States, state corrections officials estimate that between 70 and 85 per cent of inmates need some level of substance abuse treatment. But sustained, professional, supervised drug and alcohol treatment is currently available in fewer than half of federal, state, and local adult detention facilities. Juvenile correctional facilities are also staffed to serve only a fraction of those who need treatment services. In approximately 7600 correctional facilities surveyed, 172,851 inmates were in drug treatment programmes in 1997, less than 11 per cent of the inmate population and less than 20 per cent of those with addiction histories (Mumola and Karberg 2006). While some state prison systems expanded drug treatment programmes in the 1990s, these have now been cut

severely in most systems—another consequence of the recent state budget crises including, for example, a 40 per cent reduction in California in 2009 alone (Rothfeld 2009).

The injection of heroin within correctional facilities has been documented in many prisons worldwide and continues to exist, notwithstanding vigorous attempts to deter and detect the importation of drugs and injecting equipment into these facilities. Although episodes of drug injecting inside these facilities are generally far less frequent than in the community, adverse consequences (including HIV infection) are well documented. While the use of methadone or buprenorphine maintenance for addiction treatment is prohibited in state and federal prisons throughout the United States, a small number of local jails do offer brief detoxification programmes using these medications. In the past decade, some jail facilities have begun to offer methadone maintenance treatment as well.

A large-scale methadone maintenance treatment programme, serving 2000 patients per year, was established in New York City’s Riker’s Island jail in the 1970s—operated by the Montefiore health service—the first jail programme to offer this treatment in the United States. The Riker’s Island approach continued methadone for all new admissions already in maintenance at the time of arrest (mostly detainees) and initiated methadone treatment for those with sentences of less than a year. This programme paved the way for several small pilot methadone programmes in prisons and jails in Maryland, Puerto Rico, and New Mexico. But all such programmes face formidable struggles to maintain their modest gains in the face of widespread correctional hostility to this approach to drug treatment, despite the powerful evidence of its benefits elsewhere in the world.

By contrast, as of January 2008, methadone maintenance has been implemented in prisons in at least 29 other countries or territories, with the proportion of all prisoners in care ranging from less than 1 per cent to over 14 per cent (Dolan et al. 2003; Binswanger et al. 2007). In Canada, any methadone maintenance patient who is incarcerated is maintained on methadone throughout his or her time in custody, and many heroin users are started on methadone during a period of federal incarceration. Even in Eastern Europe and Central Asia, some prisons now offer methadone maintenance or a short course of methadone-to-detoxification in some pre-trial detention facilities.

Tobacco and smoking bans in prisons

While smoking bans have a clear role in many public settings such as restaurants, hospitals, and workplaces, prisons have their own idiosyncratic problems associated with smoking prohibition, such as smuggling, trading, and black markets. Recent bans of smoking in prisons in many countries, easily understood as a public health measure on the outside, clash with the important and unique place of tobacco in circumstances of confinement. The important role of smoking tobacco in prisons relates to it providing some relief from the boredom and many stresses of imprisonment—similar to the role it plays in war. Of course, in prisons, smoking also plays a central role in contraband economies—part of the black market for many drugs within prisons. Tobacco can be exchanged for goods, buy protection, and be used to pay debts for gambling.

Smoking cessation programmes therefore face the formidable ‘enmeshment of tobacco in prison life’ (Proescholdbell et al. 2008) as staff seek to rein it in with nicotine patches, bupropion,

and quitlines. Earlier experiences had examined the feasibility of psychiatric and chemical dependency units becoming smoke free. They noted the need for interventions directed at staff and patients and commented 'we are observing a tremendous amount of self-reported anger, depression and other "emotional" symptoms as most (90 per cent) of the patients are smokers and highly addicted to nicotine' (Patten et al. 1996).

Environmental issues of indoor air quality are also significant for this captive population, calling for provision of non-smoking cells and areas within prisons and environment protections which in enclosed and poorly ventilated areas are costly and may compromise security arrangements (Proescholdbell et al. 2008). In Australia, attempts to introduce smoking bans in prison have been delayed 'by legal arguments that a prisoner's cell constitutes their "home" and thus supports their right to smoke' (Butler et al. 2007). Some jurisdictions have a policy of not accommodating smoker and non-smoker inmates together, but a 2001 survey of prisoners found that one-third of non-smokers shared a cell with a smoker. The authors comment that these 'arguments need to be balanced against the human right for conditions leading to good health for smoking and non-smoking prison inmates and staff' (Butler et al. 2007). Prisoners discussing a future smoking ban in focus groups in New South Wales, Australia, spoke of 'turning the jail system on its ear' if they were prevented from smoking—there was a prison riot in Queensland, Australia, attributed in part to a prison 'non-smoking' ban. 'Concerns about adverse effects of smoking bans need to be balanced against the rights of prisoners wishing to be in a smoke-free environment' (Butler et al. 2007).

AIDS and incarceration

The global HIV epidemic now directly implicates national criminal justice policies and imprisonment—especially those related to substance abuse and illicit drug markets. Policies which involve large-scale arrests and the disproportionate incarceration of impoverished marginal populations drive HIV before them—including some of the most vulnerable populations for HIV, that is, economic and political migrants and displaced refugee populations (Spiegel 2004). Case incidence patterns are shifting rapidly as HIV enters new human populations and selects for access to new channels of transmission.

While sexual transmission remains the principal mode of transmission worldwide, injecting drug use continues to spread to new regions (most recently sub-Saharan Africa) (Mathers et al. 2010) and remains a major vector of infection as do the economic pressures and opportunities associated with large illicit drug markets in impoverished regions. These factors are allied to increased imprisonment of these populations—particularly in those nations addressing burgeoning drug markets with harsh punitive criminal justice responses. Once again the United States is an unhappy poster child for this modern plague—in large part because of its criminal justice policies and practices associated with its 35-year 'war on drugs'. In 2008, the US Centers for Disease Control and Prevention estimated that approximately 56,300 Americans are newly infected with HIV annually (Hall et al. 2008).

There is now growing evidence that mass incarceration is contributing to the continued high incidence of HIV in the United States. This relationship is particularly powerful for US racial minorities. While constituting 12 per cent of the US population, African Americans account for 45 per cent of all new AIDS

diagnoses and are now estimated to have an incidence rate eight times that of white Americans. For African American women, the magnitude of these racial disparities is even more pronounced—their HIV rates are nearly 23 times the rate for white women. Discovering the causes of such dramatic disparities in HIV rates is a very high public health priority and crucial for efforts to control the US AIDS epidemic.

Although a great deal of research already exists on US racial and ethnic disparities in HIV, much of it remains focused on individual risk behaviours while neglecting more collective phenomena, including effects related to involvement with the criminal justice system. But the US association of incarceration and the AIDS epidemic is now very strong: between 17 and 25 per cent of all people in the United States who are estimated to be infected with HIV disease will pass through a correctional facility each year, roughly 190,000–250,000 of the country's estimated total of 1 million HIV-positive individuals (Spaulding et al. 2006). Research on HIV risk is now examining the social conditions and structure of this group's community networks, especially within African American populations. Focusing on the role of the criminal justice system as an important factor driving the AIDS epidemic, these data suggest a strong correlation between the circumstances of high arrest and incarceration rates and high HIV prevalence within many African American subpopulations and their communities (Peterman et al. 2005).

The care of HIV-infected inmates is a major issue (and expense) in the prisons of nations with high rates of AIDS. Thus New York State (with over 53,000 prisoners in 2010) has about 1700 HIV-infected inmates receiving medical care using antiretroviral drugs, at an annual cost of more than \$25 million. But best estimates are that these 1700 individuals are only about one-third of the New York State prisoners infected with HIV—most of whom do not know they are infected (there is no routine testing of inmates). These HIV-positive individuals have a great need for testing programmes to identify them and to initiate their treatment as early as possible—both for their own benefit and for reducing transmission risk in the prison and, on re-entry, in their communities.

HIV rates among African Americans in New York State prisons are estimated at 5–7 per cent among men and 7–9 per cent among women, and the risk appears to carry over to their sexual partners in their home communities (Adimora and Schoenbach 2005). Recent evidence also suggests that cyclical patterns of release and re-incarceration may foster instability in sexual and social networks involving drug use, leading to broader social disorganization that increases AIDS transmission risk. In conjunction with unstable housing, untreated drug addiction, and recurrent imprisonment, a 'churn' in social networks occurs that is now typical of these communities. These destabilizing effects act within the social networks established in the prison feeder communities of many cities to produce increases in risk for HIV transmission both by sex and by drug use. Two-thirds of prisoners return to incarceration within 3 years of release and subsequently re-enter their home communities a few years later. This pattern of serial disruption spreads risk across these communities, affecting even those not directly linked to ex-prisoners. 'Risk networks' can include drug use and sexual partners of ex-prisoners, who may form a bridge between this population's periodic exposure to the criminal justice system

and the surrounding population. This connection between the widespread incarceration of African American males and high rates of HIV in many urban communities dramatically demonstrates an important long-term community health impact of the criminal justice system.

Mental health

Mental health problems are another hallmark of prison populations in the United States and elsewhere—and another source of the mounting toll of lifelong disabilities that incarceration imposes. In the United States, 400,000 to 600,000 prison inmates (15–20 per cent of all prisoners) have a major acute or chronic psychiatric disorder, and serious psychiatric cases are now recurrent in the prison system. In addition to failing to treat many pre-existing mental health problems experienced by prisoners, incarceration itself, and especially many of the increasingly punitive practices employed to control prisoners through the massive use of isolation and solitary confinement, often creates new mental health issues, that stay with and handicap individuals long past the end of their prison sentences.

Following the United States' 'deinstitutionalization' from psychiatric hospitals for the chronically mentally ill (from the 1950s through the 1970s) the strong association of drug use, addiction, and mental illness has led the US criminal justice system to become the default response for these former hospital patients—most dramatically among the poor and homeless (see Fig. 10.10.3). Chicago political scientist Bernard Harcourt notes that a growing number of individuals who were previously monitored due to mental health issues, are now being sent to jail (Harcourt 2007a, 2007b). A US Justice Department study released in September 2006 (James and Glaze 2006) found that 56 per cent of those in state prisons (and a higher proportion of those in local jails) reported mental health problems within the past year. Harcourt states that

one reason for the increase in the number of mentally ill inmates may be a trend away from institutionalizing these individuals in mental hospitals and asylums. Harcourt writes that, 'over the past 40 years, the United States dismantled a colossal mental health complex and rebuilt—bed by bed—an enormous prison' (2007b). However there is a growing movement in the United States and elsewhere to establish mental health courts to deflect these cases (often with dual diagnosis of substance abuse) to alternatives to prisons, with some positive results now being seen (Hiday et al. 2013). But this system is also very limited due to severe shortages of properly trained and supervised mental health personnel and inadequate budgets.

Homicide and suicide in prisons and jails

While in the most extreme cases, the experience of prison or jail leads to homicide or suicide, in some respects prisons are safer than many of the communities from which many inmates come. In 2002, the US homicide rate in state prisons was 4 per 100,000, and in local jails 3 per 100,000, versus 6 per 100,000 in the general, non-incarcerated population. On the other hand, the rate of suicide in US prisons (14 per 100,000) is significantly higher than in the general US resident population (11 per 100,000). And, in local jails, the suicide rate is over four times higher (47 per 100,000) than outside. These data suggest that the stresses associated with the harrowing process of recurrent arrest, police handling at booking and arraignment, and pre-trial confinement—and even brief detention in chaotic and crowded jails—are particularly traumatic, and can often prove fatal. Over 40 per cent of those in solitary confinement, a widely used disciplinary measure in US jails and prisons, develop major psychiatric disorders. Not surprisingly, while those placed in solitary represent only 5 per cent of the prison population, they account for almost half of the suicides (Mumola 2005).

UK data from a 2001 Home Office research study shows that the rates and causes of death among prisoners and offenders under community supervision were above that of the general population (Sattar 2001). Figures released by the Ministry of Justice in a report called *Safety in Custody* show that in 2011, out of a population of 85,851 prisoners, 57 killed themselves, which is 0.66 per 1,000 prisoners. In the general population of the UK, from 2006 to 2010, the registered yearly suicide rate has been stable; around 0.00017 per 1,000 population according to the Office for National Statistics' latest release (<http://www.theguardian.com/news/datablog/2012/sep/17/prison-probation-suicide-mapped>). A majority of those convicted who committed suicide in 2012 were male (96.5%), white (87%) and aged between 21 and 49 (79%). Most of them were on remand (35%) or sentenced prisoners (59%). In terms of nationality, 22.8% of the prisoners who committed suicide were non-UK nationals.

Punitive isolation and solitary confinement

The United States, with only 5 per cent of the world's population (and 25 per cent of its prisoners) now has over half of all the world's prisoners who are in long-term solitary confinement. More than 25,000 inmates are permanently in isolation in 'supermax' (short for 'super-maximum security') prisons in the United States, where they may spend years locked in small, often windowless cells with solid steel doors, let out for showers and solitary exercise in a small, enclosed space once or twice each week. A report by Human Rights Watch (2000) found that supermax prisoners have almost no access to educational or recreational activities and are usually handcuffed, shackled, and escorted by two or three correctional officers every time they leave their cells.

Supermax prisons describe 'control-unit' prisons which represent the most secure levels of custody in the prison systems of certain countries which were ostensibly designed to house the most violent or dangerous inmates—'the worst of the worst'. But many of the prisoners there do not meet these criteria. Instead, supermax prisons are a response to the rapid growth of prison populations and shrunken state budgets, which have overwhelmed the ability of corrections professionals to operate safe, secure, and humane facilities. Lacking funds to recruit, properly train, and retain adequate staff, or to provide programmes and productive activities for those in existing congregate prisons, these thinly staffed, overcrowded, and impoverished facilities breed more tension and violence. An additional 50,000–80,000 prisoners are housed in 'restrictive segregation units', many of them in isolation.

In the United States, the trend towards more long-term solitary confinement is inseparable from the explosive growth of mass incarceration. In 2009, Harvard surgeon Atul Gawande published a startling article about the use of solitary confinement in American prisons, noting that almost exclusively in the United States over the past 20 years there has been a wide-scale increase in the use of isolation (Gawande 2009). Indeed, sustained isolation has now become institutionalized as a cornerstone of America's criminal justice system and its requirement for extreme sanctions to handle the huge population of prisoners (Cloud et al. in press).

In 1995, a California federal court reviewed the state's first supermax prison, with the presiding judge noting that the conditions 'hover on the edge of what is humanly tolerable for those with normal resilience' (King 2007). This echoes an 1890 observation by a US Supreme Court inquiry on the effects of isolation: noting that

many prisoners became insane or committed suicide (Diamond et al. 2001; Hatton and Fisher 2009). Clearly the practice of locking away tens of thousands of prisoners in solitary confinement for long stretches of time has a profoundly deleterious effect on the long-term mental health of these inmates. The massive use of punitive isolation in American prisons has also become the basis for significant unrest and rebellion by inmates. In the summer of 2013 over 20,000 California inmates began a hunger strike as protest of the massive use of solitary at the Pelican Bay supermax prison and throughout the 110,000-inmate California system.

Women and prisons

Women's healthcare needs, always more prominent than those of young males, are also typically inadequately addressed in prisons. In addition to facing all the routine gynaecological, reproductive, and nutritional issues of women who are not incarcerated, the overwhelming majority of women in prisons are survivors of violence and trauma (Diamond et al. 2001; Hatton and Fisher 2009). And more than 60 per cent of incarcerated women are parents, who must deal as best they can with separation from their children and families, along with the depression, anxiety, and low self-esteem that this entails. Not surprisingly, incarcerated women suffer from serious mental illnesses at much higher rates than male inmates.

In the United States, over the last 25 years the number of women and girls caught in the criminal justice system has risen dramatically—with more than 200,000 women behind bars and more than 1 million on probation and parole. The percentage of women behind bars increased by 757 per cent between 1977 and 2004, double the increase in the incarcerated male population during the same period. The number of women in prison—along with the number of women giving birth in prison—continues to rise each year. Few get the services they need. Many of these women struggle with substance abuse, mental illness, and histories of physical and sexual abuse. Notably, despite the persistence of racial disparities, white women are now among the US groups with the fastest growth rate in US prison systems.

The increased incarceration of women for drug offences has, in some states, become a proxy for America's resurgent battles to ban abortions, a new line of challenge to the nation's Supreme Court support of abortions in the 1973 case of *Roe v. Wade* (Paltrow 2013). Legal scholar and reproductive rights advocate Lynn Paltrow notes that 'while all pregnant women have benefited from *Roe v. Wade*, today's system of mass incarceration makes it likely that if *Roe* is overturned women who have abortions will go to jail' (Paltrow 2013). Paltrow shows that many of the state increases in female imprisonment are intended to establish separate legal 'personhood' for fertilized eggs, embryos, and fetuses—as the basis for arrests and detentions of pregnant women involved in drug use and, for those who seek to go to term, seizure of their newborns under child protection laws.

Paltrow emphasizes that these cases reveal that both pregnant women who have abortions (and those who do not) are already being arrested and incarcerated at high rates (driven by the overall patterns of drug use related to larger racial disparities built into the American criminal justice system), 'creating a Jane Crow system of law that disproportionately punishes African American women' (Paltrow and Flavin 2013). Paltrow and Flavin have identified and detailed 417 cases of arrests and forced interventions

on pregnant women in the United States between 1973 and 2005, where the pregnancy was the basis of arrest and prosecution because drugs were involved (Paltrow and Flavan 2013).

Of the more than 200,000 women found in US prisons or jails each year, about 12,000 are pregnant at the time they are incarcerated. And these women and girls are subjected to harsh treatment, even when pregnant. Women, including the thousands who will deliver their babies while incarcerated, are routinely subjected to the risks of shackling—still a common degrading practice in the United States.

The privatization of correctional services

The use of privately contracted security corporations is growing worldwide. The development of private prisons in the United Kingdom, Australia, and several European and Asian nations has followed a similar pattern (Department of Justice 2006). The United Kingdom was the first country in Europe to use prisons run by the private sector, with 14 prisons today holding 13,500 inmates in England and Wales—just under 15 per cent of the total UK prison population (Panchamia 2012).

In the United States, federal and state government had long contracted out specific prison services for medical services, food preparation, vocational training, inmate transportation—as well as construction and maintenance services—amounting to tens of billions of dollars. Beginning in the 1980s, rapid growth in prison populations (resulting from the war on drugs), prison overcrowding, and rising costs, private-sector firms in the security business took the opportunity to expand massively into prisons.

The United States led the movement to employ private firms to operate state prisons and with the world's largest prison system, now leads in the proportion of its facilities contracted to private firms. While 50 per cent of the US state prison systems (with a total of 1.2 million inmates) currently use no privately operated prison services, the 25 states that do now rely on private services for over 25 per cent of the operations of their state are located mainly in Southern and Western states. As of December 2000, there were 153 private correctional facilities (prisons, jails, and detention centres) operating in the United States with a capacity of over 119,000 (Corrections Corporation of America 2012).

Several large private sector correctional service companies are publicly traded—with the Corrections Corporation of America (2013) now 'the nation's largest owner and operator of privatized correctional and detention facilities and one of the largest prison operators in the United States—behind only the federal government and three states.' The Corrections Corporation of America currently operates 66 correctional and detention facilities, including 46 facilities that it owns, with a total capacity over 92,000 beds in 20 states and the District of Columbia. Prison privatization is an aggressively entrepreneurial business—working to increase its market and buying entire prisons from cash-strapped states in exchange for 20-year management contracts and a guaranteed occupancy rate of 90 per cent (Corrections Corporation of America 2012; Kirkham 2012). Community organizations have criticized the proposals. Critics argue that the contractual obligations of states to fill the prisons to 90 per cent occupancy are poor public policy and end up costing taxpayers more than state-run prisons would.

Immigration detention

The detention of foreign immigrants who have not been admitted through legal channels has become a major job of prison systems in many countries. Asylum seekers, political and economic refugees, and victims of human trafficking now are filling prisons, increasingly used as holding areas while these populations await disposition of their cases (Venters et al. 2009).

In the United States, more people are convicted of immigration offences than of any other type of federal crime with illegal re-entry into the United States the most common charge. As a surge of new immigration offenders flow into the US federal prison system, they are being held primarily in private prisons operated by multibillion-dollar corporations that contract with the government. Privately run prisons and immigration detention centres in the United States and elsewhere often violate basic human rights of these populations. 'These are basically second-class prisoners' (Greene 2012), '[and governments are] not putting dollars into the things that keep prisoners relatively content: medical care and food, with complaints and rebellions now common due to poor conditions and inadequate medical care' (Grant 2012).

Last year the United States deported at least 400,000 illegal immigrants, a new record (Grant 2012). Arresting undocumented immigrants has become a new focus of the otherwise shrinking prison industrial complex, driving the growth of both the federal system and the use of private security firms to assume an increased role (and increased profits) from our widely contested and highly punitive immigration policies. An integral part of the increased criminalization of immigration is the expansion of prison privatization—now also becoming widespread in the many ancillary institutions that support mass incarceration—for example, youth services and half-way houses used post release, all have been found to have very high rates of violence and abuse, as well as corrupt ties to local government.

As immigration debates rage across the political landscape, the use of mass incarceration also plays a major role in the immigration debate and is responsible for vast suffering of immigrant populations. One inevitable result of the outsourcing of these operations to private providers is increased violence throughout the privately operated for-profit facilities established for immigrant detention, where detainees are granted little or no protection from the violation of their most fundamental human rights—and have scant access to legal services. There have been many uprisings at low-security private prisons housing undocumented immigrants, following complaints from prisoners about food, medical conditions, and staff members, according to a federal court affidavit filed by the Federal Bureau of Investigation (Shed 2011). A recent US press article reported on a privately operated federal prison in Mississippi holding many undocumented immigrants from Mexico where inmates attacked guards, set fires, and took hostages—with the death of one correctional officer (Shed 2011). This Mississippi prison and other private facilities also hold inmates who are *not* awaiting deportation but are in prison for illegally crossing the border, a federal offence.

In Italy, the Identification and Expulsion Center is a detention complex on the outskirts of Rome where illegal immigrants are held for months before deportation (Povoledo 2013). These detention centres throughout Europe equate immigration with

criminality, overlook the economic benefits that immigrants can bring, and fail to take account of the increasingly multicultural nature of European society.

Conclusions: the future of public health and criminal justice

The rapid rise in incarceration in the United States and several other countries from the 1970s through the 2000s has had broad effects, affecting not only those imprisoned but also their families, communities, and international politics. The expansive reach of 'mass incarceration' and its collateral effects has been accompanied in many cities by increased contact between citizens and law enforcement, increases in the time and financial impositions on individuals awaiting trial, a decline in the quality of correctional healthcare, and a reduction in available services for formerly incarcerated individuals. These complex and inter-related patterns show the ways in which imprisonment, human rights, and public health are now intimately related. With their growing concentration of vulnerable populations and their relationship to drug markets, immigration, human trafficking, border security, and global pandemics associated with sex and drugs (HIV), the international public health significance of criminal justice systems and prisons grows apace.

This examination of prisons through the lens of public health has documented the long- and short-term implications of criminal justice involvement, particularly incarceration, for public safety as well as their economic, social, and health effects on society. With this new public health basis of concern, there is renewed professional interest on the possibilities for families, schools, and neighbourhood institutions to divert individuals from criminal offending, recidivism, and the risks of jail and prison. The fiscal burdens of incarceration in the United States and elsewhere have also animated new efforts to develop and strengthen community-based sanctions as alternatives to custodial ones. These challenges, their individual and collective effects, and their concentration within the most vulnerable racial and ethnic minority communities in many nations, have motivated an intense re-examination of the 'carceral continuum' (Shedd 2011), now viewed across the multiple domains of public health, healthcare, and social services.

As a preventive discipline, public health has much to contribute to addressing the contemporary problems of criminal justice—indeed it may prove to be the most salient perspective available to us. From a preventive perspective, public health goals must now include reforms of sentencing laws (especially for drug offences) and re-examine and challenge all the basic structures of punitive patterns of incarceration from the perspective of the toxic effects of many of the forms of punishment now in effect, for example, solitary confinement. If public health can establish its legitimacy in this arena it can make very important contributions not only to health, but to fundamental human rights and help to resolve some of the greatest conflicts of modern life in our complex and ever more inter-related global culture.

Health needs assessment

Michael P. Kelly, Jane E. Powell, and Natalie Bartle

Introduction to health needs assessment

The idea of health needs assessment is, on the face of it, straightforward. In theory it ought to and could inform the planning and provision of health services in any jurisdiction. It is a simple formula: measure health, assess need, and orient services accordingly. In an uncomplicated world the assessment of health need and healthcare need would be a tool for tackling inequalities, a prerequisite for the allocation of resources and the first step in planning and evaluating care (Stevens and Raftery 1997).

In practice, however, as we will show, this neat and tidy formula raises some fundamental problems about the appraisal of, and the response to, health needs. The apparently straightforward approach requires us to confront some of the most vexing problems of definition and measurement in health and public health. Terms like health, healthcare, need, equity, equality, fairness, and justice, among others, have to be considered in detail (Gillam et al. 2012). They turn out to be far from simple or straightforward.

Needs assessment has been defined as a process which takes ‘a population-based, epidemiological and public health approach to the planning of health interventions’ (Clarke et al. 2009). That means using data about population patterns of health to do rational planning in order to meet the particular needs of all, or parts, of the community, taking account of equity, efficiency, and affordability. In principle, this approach to needs assessment might be used as the basis for planning in any health system (Clarke et al. 2009). It aspires to ‘maximize the appropriate delivery of effective health interventions or care...in an evidence based way...[to] maximize equity’ (Powell 2006).

However, ‘need’ is a slippery idea, which is not easily defined. Two broad approaches to assessing need will be outlined. The first is a very practical approach, which emphasizes measurement and tends to focus on the needs of subsets of populations and rarely tries to assess need in whole populations except in emergency situations (Clarke et al. 2009). In this view there are several levels of need: subsets in the population, groups of people with specific conditions, or a population using a particular service, for example. Both individuals and families will each generate different profiles of need. The second, broader, and more political and philosophical approach to need operates mostly at the level of total populations or whole societies and is concerned with broader questions of justice, fairness, and equity. We explore both of these approaches and identify some of the tensions between them in this chapter.

Epidemiological health needs assessment

We begin by focusing on the more practical approaches. In this view, assessment of need must include an assessment of the effectiveness of interventions to meet identified health needs (Mooney 1992; Pencheon et al. 2001). The assumption is that the relative total need can be measured sufficiently by just a few factors such as standardized mortality or morbidity rates. It emphasizes quantification and objective comparative measurement. This type of needs assessment is usually dependent on existing or available data, it seldom involves generating new information from primary research because this would be too expensive and take too long. Health needs assessment tends therefore to be based pragmatically on the routine data sources that are there already (Clarke et al. 2009).

There are a number of distinct steps. It begins with clear problem definition. To do this, two questions need to be considered. What do we want to find out about the population, and how can we go about finding it out? A series of further questions can then be asked to help clarify the process: why is this assessment needed now, who will be affected, what would the consequences be of doing nothing, how much time is available, how can the results and the recommendations be presented to maximal effect, are sufficient resources available, and how will the needs assessment be itself assessed and evaluated (Clarke et al. 2009)?

A detailed project plan identifying the component parts of the exercise should be prepared. Central to the exercise will be an epidemiological assessment which will determine how many people in the population need care and at what level and what services are available for them. It is important to identify the denominator population, that is, the total population or relevant subpopulation because otherwise it is very difficult to interpret prevalence (total number of cases) and incidence (new cases in a given time period) (Clarke et al. 2009). Collecting data like this tends to be more straightforward in developed countries. In less developed countries data systems tend not to be so reliable, although where data systems are less than optimal other options may be available (Bonnefoy et al. 2007).

Details of the structure of the population need to be built into needs assessment; the age, ethnic, occupational, and geographical contours of the local population and the patterns of health inequalities will need to be assessed and described (Kelly 2010a). The level and severity of the diseases of interest need to be examined at this stage too, along with an assessment of the prevalence of relevant risk factors—for example, levels of smoking, physical

activity, and alcohol consumption. In a population with a significant number of Afro-Caribbean people an assessment of sickle cell disease might be a particular focus of interest; in a mining community chest disease might command attention. The absolute number of people suffering from the condition, and the degree of severity can then be calculated (Clarke et al. 2009). If assumptions have to be made in the absence of data and proxy variables are used, these must be made explicit.

The next stage is to develop an assessment of the clinical effectiveness of interventions for the condition or conditions of interest. There are a variety of ways of assessing effectiveness. However, if we are concerned to determine the clinical effectiveness of a medicine, or some other kind of intervention, we will get a more accurate assessment if we use evidence in which a control is used and potential biases are minimized. If this is so, we can be reasonably sure that the observed size of the effect is a consequence of the intervention and not some other biasing factor. Some commentators suggest that using only evidence drawn from the top of the evidence hierarchy to assess clinical effectiveness is the way to do this (Clarke et al. 2009). The evidence hierarchy is a device which categorizes studies according to the methods they have used and the degree of bias which is associated with the methods. Randomized controlled trials (RCTs) and the meta-analyses of such trials rest at the top of the hierarchy as these methods are deliberately designed to eliminate bias and offer the greatest certainty that the observed relationship between the independent and the dependent variable is the consequence of that relationship, and not some other factor.

It is possible to make an assessment of the effectiveness of interventions by examining clinical trial data for its quality or bias. So it would be quite appropriate, but very time-consuming, for someone conducting a needs assessment, who is interested in the effectiveness of particular treatments, to examine RCT findings directly. An easier route is to use the evidence of effectiveness which has already been appraised for its quality in Cochrane reviews. These are produced by The Cochrane Collaboration, a worldwide network of reviewers conducting quality appraisal of primary intervention studies. Alternatively, data examined by the National Institute for Health and Care Excellence (NICE) who conduct clinical and cost-effectiveness analyses of new technologies, treatment pathways, and preventive interventions in the United Kingdom can also be consulted. The assessment of effectiveness is based on a set of principles which collectively are known as health technology assessment (Kelly and Moore 2012).

After the effectiveness analysis is complete, a synthesis of the evidence is then undertaken of the epidemiology in the local population, incidence and prevalence, underlying risk factors, treatments, and interventions ranked according to effectiveness, along with evidence of cost-effectiveness and actual costs (see later). These will, of necessity, be imprecise, but if assumptions are made explicit they will suffice as a starting point for needs assessment (Clarke et al. 2009).

Once data have been collected on the local population of interest, the next stage is to compare locally derived data with data from other places in a *comparative* needs assessment. This allows an appraisal of the degree to which local provision is consistent with what might be expected on the basis of the comparisons. This is sometimes difficult because rates of interventions vary both within and between countries, but the process is about putative

differences between the observed and the expected values rather than exactness. It is important to consult with stakeholders at this point and genuine community participation is important. Rapid needs assessment may come into play where statistical and other data are unavailable (Clarke et al. 2009). All of this is brought together in a 'case for change document' which will outline what is in place, what ought to be done, what stakeholders believe should be done, and what the community want done. Costed options are essential to inform redistribution of resources. The final step is to act on the needs assessment and implement a plan.

Health systems are complex socio-technical arrangements consisting of people, cultures, and practices, organizational structures, equipment, and technologies. Health systems are constrained, because whatever the system, the resources to fund them are finite. Because of finite resources it is not possible to do everything, to fulfil every need, or to adopt every new drug, procedure, or device. At the same time demand for health services rises because expectations of what medicine can achieve increase. People, especially in advanced societies, frequently think that they deserve or have some entitlement to—that they *need*—the best and most up-to-date medicines and procedures. The availability of a medicine therefore often creates the demand *and* the need for it—patients want it and doctors want to use it. All of this adds to the demands on the resources in the system.

Health systems have to adapt to constantly evolving sets of inputs in the form of new medicines, medical technologies, and approaches to medical and surgical interventions. Decisions have to be made about the adoption and use of these new things. In addition, the health needs of populations are complex and change. For example, the age and ethnicity distributions of populations alter. Not only do populations change, but health systems themselves also evolve. Needs assessment is one means of deciding how to allocate scarce resources to prioritize and tackle need in the face of these complexities. A needs assessment provides a basis for decision-making, which will include local knowledge and understanding of the nature of communities, their socio-demographics, and physical environment. Health needs assessment consists of a range of techniques to assess and meet need in a rational and systematic way against this background of complex and changing systems, population diversity, evolution, and increasing expectations and demand. An understanding of the social environment and the social relationships within those environments is essential to successful implementation of needs assessment.

Later in this chapter we explore some of the difficulties attached to this approach. However, it is very important to remember that applying rational principles in this way arose from an understanding that the operation of an unmanaged system in which historical patterns of supply, the generosity of benefactors, the preference of medical practitioners to live in attractive areas, and their wish to provide services that were consistent with *their* interests led to very unequal and inefficient distribution of resources. So whatever the imperfections of the rational approach, it was born out of a desire to do things better and more fairly.

Health economics and needs assessment

Over the last several decades, two important techniques have come into general use to assist the allocation of resources in the face of

scarcity in health systems: health technology assessment which helps to assess effectiveness of interventions and cost utility analysis in health economics, to help assess cost-effectiveness (Kelly et al. 2010). We have already discussed health technology assessment earlier in the context of assessments of effectiveness. We now turn our attention to the contribution of health economics.

The discipline of health economics has been profoundly influential in the approach to health needs assessment outlined in the previous section. It is possible to trace a link between the ethics that govern economic thinking and the techniques and tools that economists develop and apply. Trends and momentum for change in advanced health systems are also important because health economics has over the years operated with changing concepts of need, and approaches to, and techniques for measurement, assessment and evaluation of health programmes and interventions. There have also been some important new ideas to challenge conventional orthodoxies (Sassi et al. 2001; Coast et al. 2008).

As a starting point we look to utilitarianism—which is the ethical basis of the discipline of economics. It is a theory that holds that the proper course of action is the one that maximizes utility, specifically defined as maximizing happiness and reducing suffering. Utilitarian ideas grew out of the writings of Jeremy Bentham. Bentham had legal training and wrote on a wide range of subjects connected with creating conditions for common or social good and living in harmony. He spent much of his time travelling and tried to interest various heads of European states in his ideas. One Bentham idea that illustrates his thinking related to prisons. He suggested a surveillance system called the ‘panopticon’. The theory of ‘panopticon’ is that prisoners behave appropriately in a prison setting if they believe that someone they could see in a watch tower holding a gun, could see them at all times. This idea seems at first rather odd as a model for social good. But Bentham theorized that the armed guard would only need to make their presence felt for a short time, and after that prisoners would behave as if the armed guard was there, and would not know if in reality the guard had disappeared. He argued the ‘panopticon’ principle of surveillance of behaviour that conforms to social norms could be applied successfully to engender harmonious living among social groups and communities in society as a whole—the threat of the use of force, rather than the actual use of force.

Utilitarian ideas, theories, and techniques are concerned with the common good or the greatest happiness of the greatest number (Bentham 1834). Utilitarianism in allocation of resources for the common good of society has much to commend it. But the tools and techniques do tend to favour the status quo. They do not challenge or on the whole try to amend existing resource allocations that might be considered to be unfair or unequal. Utilitarian tools and techniques if applied without critical reflection implicitly approve existing resource allocation and aim to improve social welfare starting from that point. They make what might be viewed as conservative changes to reallocate resources, so that at least one person is made better off and nobody else worse off (Pareto 1935).

Utilitarianism, or the greatest utility of the greatest number, is the ethic that still guides economic thinking, tools, and techniques and is also central to the ethic of health needs assessment. However, at the end of the nineteenth century, the future direction of economics as a discipline was influenced by the introduction into mainstream economic theories of mathematical thinking from the physical sciences and engineering. The concerns and

subject matter of economics moved from a focus on questions of political economy, for example, generating free trade between countries for maximizing the common good and how the growing population would feed itself, to more narrowly focused, ‘scientific’ questions, for example, how to maximize utility in buying goods and services and how to maximize profits (Ormerod 1994).

Economics moved away from broad questions of how resources should best be applied for the good of society—a mix of value judgement on social welfare and observation of facts, to empirical testing of hypotheses using data—more akin to a version of laboratory experiments. For example, economists became very interested in the relationship between unemployment and inflation and used empirical testing of data to test hypotheses concerning these variables.

A new more scientific language and a range of tools and techniques emerged from economic theories which tended to distance itself from the messy details of complex behaviour. The legacy of these changes still survives within economics. A quick perusal of the main economics journals today reveals numerous articles containing strings of equations to test hypotheses, as well as outlining the intricacies and new derivatives of different economic techniques and tools and how to apply them rigorously. In addition, the need within the economics discipline to find mathematical solutions to applied problems has guaranteed survival of the basic assumptions of the economic way of thinking, that is, people, firms, and institutions are perfectly rational and behave predictably, as if they have perfect information and control over environment and events. In economics, people are assumed to be equal and social/cultural and environmental/place variations between them are not acknowledged explicitly. So when health needs assessment is defined as rational this is the underlying rationality.

Health economics has developed particular techniques and tools, in particular the quality-adjusted life year (QALY) (Cohen and Henderson 1988; Powell 2007). This is steeped in utilitarianism—allocating resources efficiently for the common good—in this instance fair allocation of health technologies and other interventions in the face of finite resources. Economic thinking is predicated on the notion that most resources are scarce and have limits, but demand on those resources is potentially infinite. This creates choice and opportunity cost meaning that once resources have been allocated and used they cannot be reallocated and used again in another way (Powell 2007). Health has been characterized as a multidimensional, dynamic concept subject to changing human expectations and revision over time (McGuire et al. 1988). The economics of health has therefore also developed over time to reflect these changes. Since the Second World War, successive generations of theorists have sought to embrace new ideas about health. For example, economic, social, and psychological aspects of health have been included to reflect changing expectations, the nature of health systems, stage of economic development, and passing time (World Health Organization (WHO) 1947, 1948, 1952). From the late 1980s in developed countries, definitions of health broadened considerably to reflect the notion that well-being is inseparable from and crucial to health, and in turn, both are influenced by society as a whole (Bowling 2001).

An important idea that has been used in health economics in this regard is quality of life (QoL) (Bowling 2001). Various instruments have been developed to measure QoL (McIntyre et al. 2008). The best QoL measures detect the cultural factors that influence

health perceptions, including the health of others in the individual's community or group, the nature and severity of illness, demographic characteristics, and social environment (Locker 1981). Debates about QoL measures have ranged over whether QoL should be measured at all (Hunt 1999), how it should be measured if it has to be (Walker and Rosser 1993; Bowling 2001), and how QoL measures might be applied (Fitzpatrick et al. 1992; Fletcher et al. 1992; Sassi et al. 2001). QoL is a hotly contested concept. However, it has been applied successfully to measure the outcome of health interventions and very importantly in units of common currency using the QALY. A distinction is made between the concepts of QoL and health status. QoL measures try to capture current broad definitions of 'health' (Walker and Rosser 1993), while health status measures include socioeconomic dimensions as well as physical factors. QoL relates in addition 'to how a person feels and functions in his or her everyday life' (Bowling 2001).

The QALY itself is used to assess cost-effectiveness of interventions. A QALY is a number indicating the size of health gain from an intervention. QALYs are conceptualized by first imagining years of life lived in perfect health with a perfect QoL. The QALY is constructed by combining estimates of life years saved (life years) by the intervention with values for utility of different health states (quality adjustment). It is created by combining quantitative information of length of survival with 'softer' information of patient perceptions of QoL (Bush et al. 1972; Weinstein and Stason 1975). The essence of the QALY is that people will trade-off length of life for QoL—they would rather live shorter lives with full QoL than longer lives in which QoL is poor. QALYs are the outcome measure used in cost utility economic evaluation. Cost utility analysis provides a standardized form of economic evaluation that focuses particular attention on the quality of the outcome produced or averted by investment in health programmes.

Cost utility analysis and the QALY have been widely used around the world in the assessment of the cost-effectiveness of new drugs and of other types of clinical interventions. But it has proved less well suited to assessing preventive public health type interventions. The literature identifies a number of conceptual, methodological, and practical difficulties in evaluating the effectiveness and cost-effectiveness of primary prevention interventions (Lorgelly et al. 2010). There are difficulties of producing evidence of cost-effectiveness for public health guidance and methodological difficulties associated with applying health economic techniques to public health interventions (Kelly et al. 2005; Chalkidou et al. 2008; Weatherly et al. 2009). These difficulties and issues spring from the focus on efficiency within economic evaluation techniques to the exclusion of the determinants of health and inequalities in health, which are central preoccupations in public health (Barendregt 2006; Lorgelly et al. 2010; Ogilvie et al. 2011). This is important because as we will show, health needs assessment is itself premised on principles of economic efficiency as well as the principle of equity. And so the same problem that applies to the application of simple cost utility analyses to preventive interventions also applies more broadly to health needs assessment.

Equity, efficiency, and health economics

Health systems may be characterized by the way they organize, finance, and deliver resources to attempt to balance competing

health and well-being objectives. Equity in the distribution of resources is the main objective of a health system where citizens have *entitlement* and equal access to the means of achieving good health and well-being according to health *need*. Efficiency in the allocation of resources—where the cost of good health and well-being is minimized and the benefits maximized—is often prioritized by governments over equity in order that the overall *cost* of a health system as a proportion of gross domestic product, is controlled. Efficiency and equity are generally viewed as competing objectives that most health systems fail to reconcile because both objectives cannot be optimized at the same time—creating an equity–efficiency trade-off. This in turn raises concerns about justice and generates philosophical arguments about where the balance between efficient resource allocation and equitable distribution of health resources to meet health need, should lie. Early forms of health needs assessment and similar approaches—social audit and rapid appraisal—attempted to establish the size of different health needs and to prioritize and allocate resources pro rata on that basis.

Health economists were critical of the early needs assessment approaches for a number of reasons. They argued that the allocation of resources according to the size of a problem can be very misleading; not all needs can be met and resources are finite. Therefore measuring need gives no guidance concerning resource allocation to meet those needs and offers no rules by which resources can be allocated across programmes and interventions. Specifically, no attention is given to costs and benefits of treatments, only to the size of problems (Mooney 1992). The practice of needs assessment changed in response to these arguments (Wright 2001). During the early 1980s, the way of thinking in health economics gathered momentum in relation to the wholesale recasting of 'need' as a concept—seeing the fulfilment of the size and volume of health needs as in direct opposition to the objective of maximizing health status through the efficient allocation of healthcare resources.

Economists argue that the size of a health need—how many people have a certain disease at levels of severity—says nothing about how to maximize efficiency in the allocation of resources, so that the ratio of marginal benefit to marginal cost is equal across all interventions (Mooney 1992; Drummond et al. 2005). Health economic techniques and tools were directed at inefficiencies in the allocation of healthcare resources and 'the need for healthcare' defined as 'capacity to benefit' from healthcare became recognized as a key aspect of health status. As a consequence, the health intervention needed in any given circumstance is a function of factors such as the level of prevailing resources, the availability and effectiveness of health interventions, and the perspective and values of those making the assessment. Over time, notions of health need have come to be defined as a result of momentum in economic discourse and debates and the development and proliferation of common currency QoL measures that reflect the outcome and efficiency of interventions to improve health and well-being.

Health economics, it is argued, provides a way of thinking logically through the problems of setting priorities for health improvement as well as offering the techniques of programme budgeting and marginal analysis to support decision-making in resource allocation. Programme budgeting can be used as an information framework to allow health services to be disaggregated into programmes which have relatively homogeneous outputs (Cohen and Henderson 1988). The information in any programme budget

will include cost or expenditure data together with an indicator of output from a programme. Services are ranked on the basis of ratio of marginal benefit to marginal cost. Marginal analysis provides rules for deciding how resources should be moved between subcategories of a programme. In terms of allocative efficiency, the concept of opportunity cost figures prominently in these techniques, where the benefit foregone is in health status.

Health systems and the equity–efficiency trade-off

We next examine the relationship between equity, efficiency, and cost, describing debates about resource allocation in Beveridge and Bismarckian health systems. These systems take their names respectively from William Beveridge whose report was used as the basis for the policies which helped establish the welfare state in Britain (Ross 1952) and Prince Otto von Bismarck who set up the first schemes of national insurance in Germany in the 1880s (Taylor 1955; Thomson 1957). We outline the ways theories of justice underpin equity–efficiency trade-offs, explaining the background to the emergence of new policy concepts and techniques of assessing, measuring, evaluating, and prioritizing efficient and equitable allocation of resources. The nature of the determinants of health and the role of physical and social environment in the improvement of community health outcomes are considered with respect to equity, need, and efficiency.

Healthcare is financed and provided free at the point of use by government through taxation in Beveridge-type health systems. Beveridge health systems differ from Bismarck-type systems in which healthcare is financed by multiple employer-based insurance schemes and taxation in which providers are privately rather than publicly owned. Both types of system, however, face the same problem of increasing demand in the face of finite resources to fund the systems. In recent decades, some reformers of health systems and health policies have attempted to create market incentives within the system to control overall healthcare expenditure, increase quality, bring down prices, and increase choice (Bevan et al. 2010)—for example, providing a choice of provider for healthcare treatments and services as a way of taking some people off waiting lists. However, the economic and social trade-off is that this comes at a price—leaving those who cannot afford to move to languish on the longer waiting list.

Alternatively, other systems that prioritize access and provide universal coverage to meet health need provide a narrower range of healthcare services because price signals to reallocate resources within the system are absent. An equity–efficiency trade-off occurs and this can create a dash from central decision-making to localism where the allocation of resources is determined by local decision-makers. Much of the tension in the balance between efficiency and equity, however, can be traced to expectations and changes over time in the common understanding of what constitutes good health and well-being in communities and countries. Inevitably, these understandings are related to stage of economic development, economic performance, and historical gross national product.

The political and philosophical approach

At the heart of the approach to needs assessment outlined so far is a relatively one-dimensional idea of need. There is an altogether different approach in the philosophical literature which defines

need as a dynamic, politically and ideologically value-laden idea. In the political and philosophical view the starting point is *unmet* health needs. It is argued that unmet need creates unfair deficits in the distribution of health and well-being among communities and populations—deficits that society should take steps to address. In this view, need is described as something that is likely to be dynamic over time as technologies, expectations, and availability of services change. Measurement of need will therefore vary in different contexts, such as in the clinical setting and at the population level. Needs assessment planning would therefore involve considerations of allocative efficiency along with social values (McIntyre et al. 2009).

But here the argument changes gear because morbidity turns out not to be a good guide to unmet need! We may posit that one person's need is greater than another's because there is a greater degree of morbidity—they are sicker. This in turn implies that one health state is more deserving than another because of the extent of the disease. It also assumes we can accurately measure the differences in disease states. This, however, may be a false premise because degrees of illness in a strictly biological or pathological sense, even if they can be measured accurately and meaningfully compared, tell us nothing about an individual's QoL with different degrees of morbidity and therefore their needs in a social or psychological sense. Some people cope extremely well with illness and have a relatively good QoL while others seem to be rendered incapable of normal social functioning with relatively minor ailments. The subjective experience of illness and an individual's response to it significantly affects their expression of need. It is difficult to measure need solely by assessing biological morbidity in any absolute sense (Locker 1981; Anderson and Bury 1988).

There is a still more difficult issue relating to health differences in populations. All health systems, and by definition all health needs assessment, have to confront the systematic differences in the pattern of health in populations. The health of individuals varies, and the health of groups of individuals also varies; so men and women, age groups, and ethnic groups show *average* differences in life expectancy and patterns of disease. The health of one country varies compared to other countries; within countries there are differences between individuals and groups. These variations occur because of biological inheritance, because of differential exposure to factors which cause disease, and because health services are not uniformly or equally spread between individuals and populations. In any case, individuals make widely different use of available services, especially preventive ones. Some people die relatively young, while others live to a ripe old age. Some people live life with multitudes of health problems and disabilities, others lead lives of a good quality and die peacefully in their beds in their 90s. So as a starting point the demands placed on health systems of these different individuals and groups vary. If we are trying in some way to meet the health needs or demands of various individuals and populations on what basis should we do it?

A straightforward answer is that we should seek to measure the needs of individuals or populations and we should allocate provision to meet the need accordingly, as that would be the fairest way to do it. But that in turn raises several questions—how exactly would we measure need? Could we do it in a way that was accurate and precise and more importantly could we do it in a way that was fair? And fair exactly to whom? To the people in need or to the people who are not in need and whom we might call upon to fund

the needs of others in greater need than them? But why should those not in need, subsidize those who are in need? Is that fair? The answer as to whether one thinks it is fair will be dictated by a political preference as well as general ideas about fairness which would in turn be influenced by other ideas about ethics, morality, duty, responsibility, and liberty for example. Is it fair to have one's income taken away to fund the needs of others? Not forgetting that some people's health needs are generated by the choices that they themselves have made in how they have lived their lives, whether they have chosen to smoke, to excessively consume alcohol and food, and to take drugs or engage in sexual practices which might expose them to risk of infection. These people have health needs, but whose responsibility is it to meet those needs? Again the answer will be influenced by other value positions.

Patterning of health differences

There is another very important dimension at play here which we have not so far explored; this is the *patterning* of health differences, which removes the discussion from the level of the individual to the level of the social or population. The differences in health experience and health outcomes, the differences in access to services, the differences in exposures to risks, and even the differences in behaviours which are health damaging are not distributed randomly or evenly in the population. Health experience and health outcomes are strongly patterned by social position. In short, on whatever measure used to assess health status, be it mortality, morbidity, or self-defined health state, the measures follow a strict social gradient. Those who are better off *on average* enjoy better health, live longer, make better and more appropriate use of services, and generally get a better deal out of health systems. Moreover, this applies under whatever arrangements for the funding of services operate. It holds true in market systems like the United States, it holds true in social insurance systems as found in much of Western Europe, and it holds true in societies where care is free at the point of use like the United Kingdom. This is called the health gradient—and is one of the most enduring and vexatious characteristics of contemporary health systems (Graham and Kelly 2004).

Comparative data for the United Kingdom and the United States illustrate the gradient. They show similar patterns of graded health differences measured by income for, among other things, self-assessed health, diabetes, heart disease, and lung disease (Banks et al. 2006). The gradient is described in many texts, reports, and papers (Mackenbach 2005; Commission on Social Determinants of Health 2008; Wilkinson and Pickett 2009; Marmot 2010; Bleich et al. 2012). The shape of the gradient varies; it tends to be steeper in societies with very heterogeneous populations and rather gentler in societies which are more socially homogeneous, but only by degree. Health differences linked to social position remain an enduring and structural feature of contemporary developed societies. In both developing and low-income countries the same features of health inequities apply although the shape of the gradient tends to be more curvilinear. In some developing and low-income countries a small affluent elite enjoy good health outcomes and the majority of the population are in a less desirable situation (Bonnefoy et al. 2007).

In broad terms the state of the contemporary world is one where health differences, however measured, prevail across all societies

and also between societies. There are absolute health differences between rich and poor societies and between rich and poor people and those not so poor, in all societies (Kelly and Doohan 2012). So here we encounter a major problem with the apparently rational calculus of health needs assessment. Whether health need is expressed in terms of health status or outcome, need (including subjective expression of need) varies systematically across the population and there are considerable health inequalities. It can be, and often is, argued that the needs of the most or the relatively disadvantaged are paramount and therefore resources should be deployed in such a way that they meet those needs first. All that would remain to be done would be to find a technical solution to the measurement of need.

In addition to the health gradient there are two other ways of looking at health differences called health disadvantage and health gaps (Graham and Kelly 2004). Health disadvantage simply focuses on differences, acknowledging that there are differences between individuals, distinct segments of the population, or between societies. It is a descriptive and non-judgemental approach. The health gaps approach, in contrast, focuses on the differences between the worst off and everybody else, often inviting the conclusion that those who are not the worst off enjoy uniformly good health. The gap approach also invites the conclusion that this state of affairs is wrong or unfair.

A gap approach and a gradient approach lead to rather different solutions. Conceptually, narrowing health gaps look to actions which will improve the health of the poorest regardless of the rest of society. Such an approach would be one which achieved both an absolute and a relative improvement in the health of the poorest groups. The health gradient approach takes, as its starting point in contrast, the acknowledgement that the penalties of inequities in health affect the whole social hierarchy even though they increase from the top to the bottom.

Gaps and gradient approaches lead to quite different assessment of need and how to meet those needs. It may seem counterintuitive, but if policies or actions only attempt to target the needs of the neediest at the bottom of the social hierarchy, there will be little or no impact on health inequalities across the rest of society (Rose 1985, 1992). This is because inequities in health will still exist, the social determinants continue to exert their malign influence, and the health needs of the majority of the population remain unattended to. The alternative approach advocated by the Marmot reviews, for example, and the WHO (Bonnefoy et al. 2007) involves a consideration of the whole gradient in health inequities rather than only focusing on the health of the most disadvantaged. An effective policy is one that meets two criteria. It is associated with: (1) improvements in health (or a positive change in its underlying determinants) for all socioeconomic groups up to the highest, and (2) a rate of improvement which increases at each step down the socioeconomic ladder. In other words, a differential rate of improvement is required: greatest for the poorest groups, with the rate of gain progressively decreasing for higher socioeconomic groups. It locates the causes of health inequity, not in the disadvantaged circumstances and health-damaging behaviours of the poorest groups, but in the systematic differences in life chances, living standards, and lifestyles associated with people's unequal positions in the socioeconomic hierarchy (Graham 2004a, 2004b, 2006; Graham and Kelly 2004). The significant caveat is that where the health gap is both large and the population

numbers in the extreme circumstances are high, a process of prioritizing action by beginning with the most disadvantaged would be the immediate concern.

From health inequality to health equity

The gradient leads to some other questions. Does it matter that there are patterns of inequalities in health? Why should we seek to remedy this state of affairs? Why use the instruments of health service provision to deal with this problem? Why conduct needs assessment to try to change the gradient? After all, all societies demonstrate a gradient to some extent. Even though health differences are clear, a case can be made that over the last century and a half, things have improved for nearly everyone—at least in the developed West. Rates of infant mortality are at an historic low and life expectancy has never been greater. Furthermore, while *average* patterns of morbidity and mortality in different social groups and populations may be clear, there are wide variations between individuals. In short, not all well-to-do people live to a healthy ripe old age, and not everyone who is disadvantaged dies young. To be human is to know that we will eventually die and that the manner and timing of our death is in almost all circumstances beyond our control whether we are rich or poor. So is it the case that patterned average differences in *early* and largely *preventable* death and suffering are unfair and unjust just because they are theoretically preventable—particularly when there is no necessary inevitability that relatively disadvantaged people should die earlier than anyone else? There is no straightforward answer.

A number of writers have explored the theme of injustice in this context. The WHO has had a long-standing interest in the matter. The WHO's Commission on the Social Determinants of Health used a series of definitions to clarify things which were based on the work of Whitehead (Whitehead 1992; Whitehead and Dahlgren 2006) and Solar and Irwin (2010). A distinction is made between health inequality and health inequity. Health inequality is defined as *health differences which are not avoidable or preventable, are not the consequence of human actions and activities, but are based on genetic or constitutional individual differences, age or biological sex*. These are sometimes also referred to as variations (Kelly et al. 2007). Health inequity, in contrast, is defined as *unfair and avoidable or remediable differences*. Health equity in turn is defined as *the absence of unfair and avoidable or remediable differences in health among social groups* (Solar and Irwin 2010). The italics highlight the difference in definitions. It is particularly important to note that the difference in definition between inequity and inequality is not used universally and many writers and commentators use the two terms as synonyms. Also the distinctions between individual differences which are based on human biology and differences arising from interaction between an organism and an external man-made hazard are in reality difficult to draw in anything other than an analytic sense. Empirically the divides are much fuzzier than these definitions suggest. However, as a way of beginning to find some clarity the distinction is helpful. Equity and inequity are not products of nature; they are the products of human actions and, as they are socially, economically, and/or politically produced they are, theoretically at least, modifiable. The defining characteristics of equity are fairness and justice; the defining characteristics of inequity are unfairness and injustice (Whitehead and Dahlgren 2006).

Fairness and unfairness can be conceptualized as absolutes; something or some state of affairs is either fair or unfair—it cannot be both at the same time. But thinking like this in absolute terms misses the point that fairness and unfairness are not properties, things or states of affairs, but are about *relationships* between people. Fairness and unfairness arise as a consequence of the nature of the *relationships* between people and the ebb and flow of human affairs. So too justice is not a simple measure of equitable distribution of resources according to need, but is about the nature of relationships in society.

Justice may be understood in terms of the properties of people, their conduct, the rules that govern their affairs, and the characteristics of institutions—an absolute definition. The alternative is a *relational* concept of justice which concerns itself with the 'justness' of relations between people—X is unjust to Y (Pogge 2003). Such relations involve human agency, purpose, and motive. From a relational point of view justice should not be about fair distribution; it should be about seeking to identify the agents responsible for the social arrangements that determine the shape of human relationships (Pogge 2003).

Health equity may be conceptualized in distributional or relational terms in the same way that justice can be. The distributional approach is focused on the goal of equalizing good health across society—which is really the underlying value position of most health needs assessment and much of the discourse about health inequity. The relational view is about the balance between the harms inflicted and harms mitigated or prevented. In the relational view, social institutions and those responsible for them should have more concern to prevent and mitigate those things they cause themselves and for which they are responsible, rather than those things which are outside of their control (Pogge 2003). So the real issue in relational terms, with which equity should be concerned, is not the fact that health is differentially distributed, but that social systems contribute to the differential distribution of health and disease. Poverty is the greatest contributor of all to ill health. Organizing economic arrangements so that they do not generate the conditions of poverty which generate ill health is thus, it may be argued, a moral duty. Therefore focusing on assessing need without looking at the wider determinants of the causes of inequity in the first place, is misguided. The global economic order is responsible for the generation of ill health and health inequities (Pogge 2003), and social arrangements that have negative effects on health are unjust (Venkatapuram 2011).

In a celebrated paper called 'What is the point of equality?' Anderson (1999) outlined a number of the problems associated with the distributional concept of equality. She warns against the notion that we can construct institutions to make them more equal and fair, not least because this tends towards greater and greater state interference in the lives of the citizenry. She notes that one of the dangers associated with egalitarianism and the distributional approach is that it pushes the limits of the state further into the lives of ordinary people. This is a particular danger if states become concerned with equities of health rather than oppressions of the powerful against the powerless. In other words, focusing on rearranging healthcare resources to make the patterning of health more equitable is rather like moving deck chairs around on the deck of the Titanic after she hit the iceberg—largely irrelevant and pointless when the ship is sinking. 'Recent egalitarian writing has become dominated by the view that the fundamental aim of

equality is to compensate people for undeserved bad luck—being born with poor native endowments, bad parents and disagreeable personalities, [and] suffering from accidents and illnesses’ (Anderson 1999). This, she says, is not really the issue. We should instead be preoccupied with ending oppression (which is a relationship) rather than trying to ensure that everyone gets what they morally deserve. It is about creating a community in which people have equality in relationships with one another (Anderson 1999). She argues for democratic equality which means that all law abiding citizens are allowed effective access to the social conditions of their freedom. Anderson criticizes the view that the purpose of distributive justice is to compensate people for their misfortune. Her argument strikes at the heart of the idea that health inequities are simply unfair; her position is that while life may be unfair, bad luck is not at the heart of it—it is the relations between people and the way that they treat each other that is much more fundamental.

Anderson draws our attention to the fact that the concept of equality can mean a number of different things depending on the underlying political value position and the epistemological assumptions of the theory. So a utilitarian seeking to maximize the greatest happiness of the greatest number would see things differently to a Marxist seeking absolute parity in access to wealth, for example. She demonstrates that equality is a rationalist rather than an empiricist concept, meaning that the discourse about distributional equality and health equity is premised on the manipulation of ideas and the contest between different ideas and political philosophies, rather than being something that can be demonstrated by empirical methods (Millican 2007). True, protagonists will appeal to empirical evidence about poverty and about wealth to justify their arguments, but in the end, much of the discussion about equality is grounded in ideal discussions of future desired states and institutions and the manipulation of ideas to justify that view, rather than the case being made that empirically things could be changed by doing *x*, *y*, or *z*. Where *x*, *y*, or *z* are suggested, they are selected on the basis of ideological preference, not empirical science.

Bernard Williams argued that the proper grounds for the distribution of healthcare are health need (Williams 1962). This he saw as a fundamental truth (Wolff 2007). Others have argued that this is not a fundamental truth at all. Nozick has argued that the focus on need, common among egalitarian thinkers, is to define people quintessentially as consumers. The task then becomes one of finding the best way to ensure the fair distribution of available goods to consumers (Nozick 1974). The problem of course with this approach, is that this casts humanity into a fundamentally passive role and it doesn’t consider individuals as active producers (Wolff 2007). Williams also argued that there is nothing about need itself intrinsically that should motivate action on equity (Williams 1962). What society decides to do for people, particularly in health need, depends upon a moral and ethical stance.

Another argument is that the goal of fair distribution should be treating the worst off as well as possible rather than flat equity (Wolff 2007). John Rawls argued that difference in the distribution of primary goods such as health is tolerable, so long as the welfare of the most disadvantaged is looked after (Rawls 1971). Dworkin takes this argument a stage further. He suggests that we need to determine why the worst off are in that position. Dworkin asserts that some may not be able to work because they are unable to find work; but others may decide they do not want to work. Dworkin

also notes that some people’s needs are greater than others (someone who is severely disabled has greater need than someone who is able bodied for example—although as we noted above this is a highly questionable first premise). But needs, Dworkin notes, are compounded by taste. Some people’s needs are determined by expensive tastes say for drugs or wine or jewellery. Dworkin therefore distinguishes between brute bad luck and circumstance from optional bad luck involving some degree of culpability for being in need. For Dworkin, this distinction is all important, as it is his view that the state has a duty to deal with the former, but not the latter (Dworkin 2000; Wolff 2007).

Some philosophical reflections

Health needs assessment is not value neutral, it is premised on a number of philosophical and political concepts. It is helpful to explore the arguments relating to these ideas not least because although they are fundamental to health needs assessment the conventional literature about health needs assessment seldom considers the underlying assumptions and issues in detail. This is particularly so with respect to the central importance of utilitarianism and its contested place in the philosophical canon. The discussion is made all the more confusing because many of the relevant ideas like justice, equality, fairness, and so on are in common as well as technical philosophical usage and the meanings attached to common sense understanding of the words and the technical vocabulary usage are seldom commensurate.

Another very intriguing characteristic of the literature—a literature after all which readily uses terms like justice, fairness, equality, is that with the exception of Sen (more of whom later), the origins of the arguments about justice and need are conducted entirely without reference to their antecedents in Christian or Islamic teachings or the teachings of the other major world religions. The secular attempts to define the equal society, justice, and fairness struggle in this regard to find a moral or ethical point of reference. The other very odd thing is that conventional political philosophy has, down the years, actually paid scant attention to health and health inequalities and issues of distribution of healthcare resources (Venkatapuram 2011).

At the heart of the debates about equity and health inequity in contemporary society is, as we saw earlier, social justice. Health inequities are considered by many commentators to be unjust and unfair and this is advanced as a reason for allocating resources following needs assessment, more fairly. Just as utilitarianism is central to health needs assessment, it has also been central to theories of justice too viz. what produced the greatest happiness in the greatest number was considered to be socially just (Venkatapuram and Marmot 2009). This absolute or distributional approach to justice was based on a highly individualistic model and was premised in turn on the individual as the unit of analysis and not the alternative which is the relational conception of social life. The solution in the utilitarian view of the world is fair distribution and systems which can efficiently distribute resources, a principle at the very heart of health needs assessment. The utilitarian argument overlooks, by virtue of its basis in the maximization of utility, not only the fact that humans are motivated by a variety of things, not just maximizing utility, but also love, social conflict, human venality, and sheer and utter evil, and it doesn’t seem to have a concept of the social. In other words, individual utility

maximizing motivated agents are the focus of the argument, not social relations between people. This individualistic approach chimes with medicine.

Medicine has as its principal focus, pathology in the individual human body. This means that, with only a few historical exceptions, the intellectual interests have been oriented to phenomena located in individual human bodies or minds with pathology measurable in ways that reflect the individual and individual variation from some notion of what is normal or healthy (Antonovsky 1985, 1987; Carter 2003). This approach received an enormous boost with the rise of germ theory and with the fantastic successes of the isolation of pathogenic microbes and then antibiotics to combat them. Of course medicine has other foci too; especially body systems, but the variables and phenomena of particular interests are individual. The pathogenic paradigm, in which the fundamental rationale is isolating the specific cause (pathogens) of specific outcomes (pathologies), reinforces the individualistic approach. Psychology has likewise made its main focus the individual so measures of intelligence, personality, quality of life, all reside in the individual or are characteristics or properties of individuals. The approach is about the degree to which things go wrong in individual bodies and minds and the preceding causes of the pathology. Need as an individual property is an obvious next step in this way of thinking.

Economics and especially health economics has bought into this individualistic paradigm in a big way. The QALY and the application of cost utility analysis and health technology assessment are deeply infused with an individualistic orientation. The greatest happiness of the greatest number is the utilitarian philosophical view which sits very comfortably with the individualistic paradigm because it conceptualizes the notion of the good as the aggregate of lots of different individual utilities. The ontological consequence of this—that is, the assumptions made about what constitutes human life and how and why it is the way that it is—is the idea that the essence and meaning of human existence can be captured by isolating these individual characteristics and seeing how they connect to each other. So individual characteristics as different as height, weight, blood pressure, bone density, hair colour, IQ, biological sex, and size of tumour, for example, can each in turn be linked to the presence of other characteristics in the individual like health of mother *in utero*, poor nutritional status in childhood, genetic coding, parental heredity, age, chromosome structure, and exposure to tobacco smoke. The causal link is from one individual characteristic to another.

Now all of this is intuitively meaningful—in the modern Western world the individual and the individuated self are touchstones of the way we live our lives and the way the state regulates our lives—we have, for example, individual national insurance numbers, passport numbers, birth certificates, tax codes, and genomic structures. Individual variables seem natural. Further in medical terms there have been some remarkable successes in isolating disease mechanisms and offering curative technologies using the individual approach—although far less than the popular imagination often supposes—using these principles.

However, there are two fundamental objections which suggest that another way of viewing things might be helpful. First the individualist approaches dehumanize people—people are reduced to some subhuman characteristic—a number, a genetic code, a pathological organism, a utility. But second, and more importantly,

and notwithstanding the advances that have followed in the wake of some of the individualistic connections which have been made, above all it ignores or relegates the fact that humans live in groups and that those groups are in relations with each other and that membership of those groups is a defining characteristic of identity and of profound importance to most people—one's family, class, tribe, caste, gender, ethnicity, and nationality are all paramount social markers in life. Moreover, the relationships within which we live our lives, the relations with other people and the relationships within and between different groups, shape the nature of our human selves, our experiences, and our behaviour. The defining characteristic of human life is belonging—to be a member of multiple groups and communities. We live our lives in a network of interlinked and overlapping relations with others. Knowingly or not, the desire to belong has far-reaching consequences on the types of behaviours that we adopt and the choices that we make. Not surprisingly, therefore, the effects of social exclusion or isolation from social groups are of paramount importance when trying to explain the health of an individual.

What this makes us pause and reflect on is not that the individual understanding of human affairs is unimportant—that would clearly be an absurd position to adopt. Rather it is that a full understanding of the human condition requires additionally another set of concepts—which capture human relationships—relational concepts—in order to develop a rounded account of human life. And moreover inequity and injustice are best understood in relational not individualistic terms.

Social theorists have grasped the idea of a well-rounded approach very neatly in the conception of the dynamic interaction between agency and structure. The idea of agency is that we are all unique biological, psychological, and physical individuals. We all engage in individually motivated actions and behaviours which are in part the results of our unique individuality. But the sum of all human behaviours is social structure which is the consequence of the millions and billions of human relationships that are the medium for individual actions. Those structures or webs of human relationships are relational and in turn they constrain, drive, and facilitate individual human behaviour. So we have individual behaviour, the medium for its expression which are human relationships, and social structures, which are the sum of all those relationships, which in turn impinge on and delimit the possibilities of individual behaviour (Giddens 1979, 1984; Elder-Vass 2010).

This rather abstract approach allows us in turn to consider some of the thorny problems at the heart of health needs assessment. Thinking of the dynamic interaction between agency and structure moves us beyond the methodological individualism of traditional epidemiology and therefore of health needs assessment and provides an escape from the individual level of explanation (Frohlich et al. 2001). This in turn allows for a fuller understanding of the dynamics of the development of health inequalities (Abel and Frohlich 2012).

This way of thinking has been linked to what is called capability theory (Sen 2009). The core characteristic of capability theory is its focus on what people are effectively able to do within relationships with each other (Abel and Frohlich 2012). Individuals being able to engage effectively in what they really want to do, is the core idea. These engagements include being active, healthy, and being able to work but the list is not limited to these activities. In the capability approach, resources and their fair distribution to individuals (the

focus of the traditional utilitarian approach) are not the central interest. Resources are not ends in themselves they are means to ends. And neither are resources reducible to monetary utilities. People's abilities to realize their life goals and plans are the focal point. In the capability approach, the issue of justice, fairness, and need does not apply to resources per se but to the range of options for agency—the capabilities (Abel and Frohlich 2012).

Sen is a seminal thinker in relation to these arguments. He makes the case for a dynamic approach to social justice. He has argued that to think about justice in terms of fairness is a major shift away from the traditional ways that philosophers have thought about justice. This is because they were locked into the utilitarian/distributional tradition (Sen 2009). This is important in the context of needs assessment which is fundamentally utilitarian and implies that through its rationality and market allocative efficiency it will be possible to deliver fairness by market redistribution. This follows a tradition which goes back, according to Sen, to the Enlightenment. The utilitarian position is a rationalist position writ large, that is, a position which is about the manipulation of ideas, rather than the observation of empirical facts (Millican 2007). The ideas about social justice which are being manipulated are that it is possible to design institutional arrangements that will deliver justice and this will be the basis of a perfect society. For Sen, justice is a relative concept and is about relations between people. Justice is a process, an aspiration; it is about advancing justice or reducing injustice. It is not about finding or describing the perfectly just society. Because social structures and their properties emerge out of human relationships, it means that to try to legislate to change social systems to make them more just or fair can only ever be partially effective. In a sociological sense justice and injustice are properties of social systems not abstract transcendental things that can be made by social actors. Sen's approach is comparative, plural, iterative, dynamic, and acknowledging of alternatives.

Justice in this view is not a given—a rationally derived static universal principle. It is about relations between people and arises as a consequence of social action and social structure. Therefore injustice will also arise socially in social interaction and is decided upon morally or metaphysically. The judgement about whether the relations between people, such as differences in health, are just or unjust is a value judgement. In short, seeking to bring about equality in relation to health by the utilitarian redistribution of resources is never likely to work, or to produce fairness and justice because justice is not a quality of individuals or institutions. Equality is about human relationships and the utilitarian approach at the heart of health needs assessment is based on an alternative individualistic ontology.

Sen's argument is that theories of justice major on something; it could be happiness as in the case of classical utilitarianism, and it could be resources or income. Sen argues that in contrast to these utility-based or resource-based lines of thinking, individual advantage is judged in the capability approach by a person's capability to do things they have a reason to value. A person's advantage in terms of opportunities is judged to be lower than that of another if they have less capability—less real opportunity—to achieve those things that they have reason to value. The focus is on the freedom that a person actually has to do this or be that—things that they value doing or being (Sen 2009). Sen's approach is about human life and the opportunities for living—living as

against just existing. Justice for Sen cannot be created by social institutions. Justice should aim to reduce injustice, that is, change the nature of the relationships between people, rather than aiming to produce a perfectly just society.

Conclusion

Health needs assessment can be seen as a highly rationalist, straightforward means of identifying health needs, of linking needs to patterns of health inequities, of marshalling appropriate resources to match those needs, and then deploying resources accordingly. And of course that is what it aspires to do. But that aspiration is based on the traditional rationalist approach of utilitarianism and in turn on an individualist ontology. Need, as we have shown, is not a static, objective thing. It is therefore intrinsically difficult to measure and as soon as one starts to try to capture the idea fundamental questions about fairness and justice are raised.

The objective and measurable concept of need is located in an individualist ontology. When we think instead in relational terms about equity, justice, and human capabilities a different perspective is possible. Capabilities theory captures the idea of equity in a far more nuanced way than individualistic utilitarian accounts. It also offers a more complete way of understanding how we might rethink health needs assessment.

So rather than seeking to measure individualistic objective variables and then seeking to apply resources accordingly, the relational capabilities approach bids us to think about the relations between service providers and users in a much more novel way. It requires us to not try to match resources to a completely slippery and spuriously objective concept of need, but instead makes us consider the nature of the relationships between people and services.

Maximizing health outcomes, a utilitarian fundamental principle, may not be what social justice requires and alleviating injustice may require more than maximizing efficiency (Venkatapuram 2011). The argument then hinges on several fundamental things: the degree to which the structure and organization of services permits people to meet their own capabilities, the degree to which it allows human potentials to be realized, and the degree to which the relationships with services do not distort or alienate people from themselves or from others. The capability approach privileges human functioning, not maximizing utility or achieving an idealized and biologically improbable disease-free state (Venkatapuram 2011).

This means that service design should reflect and respect human dignity; this means respect for an individual person, but at the same time acknowledging the limitations which disease and disability genuinely impose on people while recognizing that there is not a direct cause and effect linear relationship between disease state and social functioning. It should acknowledge the fact that illness and disease by their very nature tend to exacerbate disconnectedness between the person and their normal role responsibilities, their primary social attachments, and their desired capabilities. The experience of disease and disability can also produce a profound separation of the individual from their sense of self or their sense of who and what they want to be. The capability approach therefore requires us to respect the lifeworlds of ordinary people and work with them to build their skills, assets,

and capabilities (rather than focusing on their deficits and trying to correct them via redistributive activities). These skills, assets, and capabilities allow them to manage their lifeworlds with minimal interference. The kinds of skills which enhance capabilities include interpersonal relationships, technical skills to manage the routine aspects of social and economic and domestic life, skills to develop emotional and psychological resistance (often referred to as coping or resilience mechanisms), and an ability to make life seem meaningful. These skills enable people to manage the routine travails of ordinary living as well as the more significant life events which engulf everybody from time to time (Kelly 2010b). It also allows people to manage the material lifeworld they inhabit. This is important because the material and psychological lifeworlds mediate the stressors—physical, psychological, and biological—which assault the human body periodically. The greater the ability people have to control their lifeworlds, the greater the resilience they will have. Skills to control the lifeworld are quintessentially capabilities. The inability to exert that control forms the basis of the patterning of health inequities because the ability to exert control is not spread uniformly through the population. Following Sen's prescription, we should seek not to measure need in a potentially spuriously scientific way, but rather acknowledge that the *total* population, all of us, are in need of strengthening our capabilities. Further it is relatively easy to predict where the need to develop more capabilities and skills is greatest and that is among the poor, the disadvantaged, subgroups and minorities, and people with disabilities. Efforts to develop and build the skills and capabilities should be proportionately, but not exclusively, focused on these groups. The level of self-empowerment to help to realize these capabilities needs to be appropriate for the individual. This is an important consideration when deciding where to deploy resources.

Moreover, upstream efforts need to embrace a public health preventive approach; an education in basic skills for living, appropriate role modelling as the basis of the most appropriate skills for human interaction, appropriate deportment, manners, respect for others, management of emotions, and the development of an appropriate sense of self and identity are the basics of human socialization. This means that the early years are particularly important and that taking the edge off encounters between people that are destructive and harmful is paramount.

While all of this plays out on life's grand stage, it must also apply to the way health services are provided and delivered. If services are organized around allocative efficiency alone and neglect the sense of self, the identity, the skills required to negotiate the system, and they alienate patients and public from and systematically deskill the recipients of care, they meet no one's needs at all, and serve only to make the patterns of inequities worse. They become, in other words, a contributor to the problem, rather than a solution to the problem. Unfortunately, the utilitarian approach with its individualistic ontology, and its emphasis on ideal rationality, is focused on a question, which on the face of it is not unreasonable, of how to match resource deployment to need. This is in fact the wrong question, so it often ends up doing exactly the opposite of what it is trying to do and making matters worse.

None of this should be taken to be a yet another Utopian recipe for the perfect society. Human venality, greed, jealousy, laziness, prejudice, incompetence and even evil will always be part of the human condition, resources will always be scarce and groups will compete, sometimes viciously, for those resources. But the

development of human capabilities allows the harder edge of human existence to be ameliorated. It does mean though that the temptation to try to find purely rationalist solutions which can only ever work in theory, or indeed in Utopia—nowhere—rather like transcendent theories of justice, must be resisted. It must be acknowledged that it is about human relationships and allowing those relationships to be as humanly meaningful and fulfilling and permitting of enhancing human capabilities as possible. The most important task in a good and just society is to prevent the erosion of those things which protect and maintain human capabilities. It is to protect the virtuous and the virtues and to enhance them where possible and to protect them by supporting social arrangements which facilitate that. Relationships cannot be legislated for, nor made to happen by complex processes of resource allocation. Justice and the social arrangements that maintain relationships are in the end the emergent properties of social relations. Those relations must be cultivated in a humane, and as far as possible, just way that protects and enhances people's capabilities. This must be the prerequisite for any state wanting to deploy its healthcare resources in a way that is both effective and meaningful. Building capability into service design is a fundamental prerequisite.

Prevention and control of non-communicable diseases

K. Srinath Reddy

Introduction to prevention and control of non-communicable diseases

In September 2011, the United Nations (UN) held a High-Level Meeting on Non-Communicable Diseases (NCDs), involving heads of state and other senior government functionaries from across the world. The only prior occasion that the UN had convened such a meeting on a health-related issue was in 2001, when a concerted global response to the HIV/AIDS epidemic was framed. It was clear from the political resolution adopted at the 2011 summit that the NCDs were being recognized as a similar grave threat to global health and development, warranting concerted global action for prevention and control (UN General Assembly 2011).

The transition between 2000 and 2015, in the framing of global development goals, also illustrates how NCDs have finally emerged on the radar screen of global health priorities. Action on NCDs, including tobacco control, did not feature in the Millennium Development Goals of 2000. This was despite the fact that NCDs had already become the leading cause of death globally towards the end of the twentieth century and tobacco had claimed about 100 million lives in that century. However, all of the groups working to draft the post-2015 Sustainable Development Goals (SDGs) have acknowledged the need to incorporate the prevention and control of NCDs within the ambit of any health goal proposed for inclusion among the SDGs (International Institute for Sustainable Development 2013; Leadership Council of the Sustainable Development Solutions Network 2013; UN 2013).

What are non-communicable diseases?

Despite all this attention, most people, many policymakers, and even some health professionals do not know what the term 'NCDs' means and includes. The descriptor emerged initially to indicate diseases which were considered to be non-infectious in origin and spread, at a time when global health was mainly concerned about infectious diseases. For the purpose of the UN high-level meeting, the World Health Organization (WHO) proposed to restrict the term to four major disease groups: cardiovascular diseases (CVDs, which include stroke), diabetes, cancers, and chronic respiratory diseases (such as asthma, emphysema, and chronic bronchitis). These four groups of disorders, though very different in their

clinical profile, are linked by four common risk factors: tobacco, unhealthy diet, physical inactivity, and alcohol.

Many find the term 'NCDs' unsatisfactory for several reasons. First, some of the cancers (e.g. cervix, liver, and stomach) and some forms of heart disease (e.g. rheumatic heart disease) are linked to viral or bacterial infections. Second, in the socio-epidemiological understanding of disease causation, disease-causing agents like tobacco, alcohol, and unhealthy foods are marketed aggressively across countries and can be considered 'communicable'. Behaviours too are vulnerable to change under the influence of cultural and commercial messages that are communicated to people. Third, where do mental illness, vision and hearing disorders, haemoglobinopathies like thalassaemia, musculoskeletal and gynaecological disorders, and some renal diseases fit in, if the term is restricted to four groups of diseases?

Other terms which have been used to describe NCDs are 'chronic diseases' and 'lifestyle-related diseases'. These too are unsatisfactory. There is nothing 'chronic' in the clinical picture of acute myocardial infarction (heart attack), stroke (brain attack), or sudden cardiac death, even if the underlying pathology may have had an insidious growth. Labelling NCDs as 'lifestyle-related diseases' places the blame on individuals, without taking into account the social and economic factors that operate at the population level, influencing personal behaviours and often overriding informed choice as the main determinant.

Would it be better to choose a descriptor that is more directly linked to the common risk factors than to a disparate group of diseases? A term like 'diet, inactivity, tobacco, and alcohol-related disorders' (DITARDs) will clearly spell out the causes that need to be countered to reduce the NCD burden and may shape the attitude of health professionals, policymakers, and people to emphasize prevention instead of focusing mainly on disease management as at present.

However, it must be recognized that the UN summit has now legitimized the term NCDs in the global health parlance. The nomenclature has finally been registered on the consciousness of national policymakers across the world and, therefore, has come to stay. Global public health must accept the term as indicative of four major disease groups which are partly but not wholly linked by four risk factors and their determinants, and not quibble about which diseases are in or out. Conditions like mental illness will surely need attention and action, as will injuries and disabilities,

but the ambit of NCDs is now defined by the criteria set by the WHO and UN.

Global burden of non-communicable diseases

The WHO estimated that NCDs accounted for 36 million deaths in 2008, contributing to 63 per cent of the 57 million deaths from all causes worldwide (WHO 2011a). About 80 per cent of the NCD-related deaths occurred in the low- and middle-income countries (LMICs) which also accounted for 90 per cent of the 9 million NCD-attributable deaths that occurred below the age of 60 years (WHO 2011b). Even when deaths under 70 years of age are considered, 48 per cent of the NCD related deaths in LMICs occurred below that age in 2008, in comparison to 26 per cent in high-income countries (HICs). The Global Burden of Diseases study 2010 (GBD 2010) estimated that mortality due to NCDs increased from 57 per cent of total mortality in 1990 to 65 per cent in 2010, with a continued high burden of deaths in middle age in the LMICs (Lozano et al. 2013).

Comparisons of NCD mortality, across countries or regions, provide varying profiles, depending on which statistical measure is used. When absolute numbers of NCD-attributable deaths are considered, the LMICs account for the largest fraction because of their cumulative population size. The HICs presently have higher proportional mortality rates (NCD deaths as a percentage of all deaths, within countries) but these too are rising in the LMICs. The highest proportional mortality rates due to NCDs are presently seen in Eastern and Central Europe. Due to the large proportion of deaths occurring at a young age, LMICs have higher age-standardized mortality rates for NCDs, when compared to countries like the United States, Australia, or New Zealand. In every region of the world, other than sub-Saharan Africa, NCDs account for a higher proportion of deaths than the combined contribution of communicable diseases, pregnancy-related events, and nutritional deficiency. Even in sub-Saharan Africa, the age-standardized mortality rates of CVDs are higher than those in HICs but that burden is obscured by the overwhelming effect of HIV/AIDS, malaria, and tuberculosis on proportional mortality. Indeed, the highest rate of rise in NCD related mortality over the next two decades is projected for Africa (WHO 2011c).

Among the NCDs, CVDs are the most prominent, accounting for 48 per cent of all NCD-related deaths in 2008. This group features two dominant disorders, coronary heart disease (CHD) and cerebrovascular disease (stroke). In addition, there are several other cardiovascular disorders like rheumatic heart disease, cardiomyopathies, hypertensive heart disease, and peripheral vascular disease. Cancers contributed to 21 per cent of NCD deaths, chronic respiratory diseases to 12 per cent, and diabetes to 3.5 per cent. Since deaths in people with diabetes are often due to CHD or stroke, its contribution to NCD mortality is larger than the directly attributed fraction suggests.

Apart from mortality, disease burdens are also estimated in terms of disability-adjusted life years (DALYs). This is a summated measure of years of life lost due to death from a disease and a measure of 'life years lost' to years of disability accruing from the disease, weighted for the extent of disability. In 2010, NCDs contributed to 54 per cent of total DALYs lost globally due to all health disorders combined. This represents a substantial increase from

the 43 per cent of DALY loss attributed to NCDs in 1990. In the two decades between 1990 and 2010, DALY loss from CVD rose by 22.6 per cent, cancer by 27.3 per cent, and diabetes by 69 per cent, while the DALY loss due to chronic respiratory diseases decreased by 2 per cent (Murray et al. 2013).

There are considerable variations across the world in the profile of NCDs. In Africa, China, Japan, South East Asia, and some countries of South America, stroke is the dominant form of CVD. In others like the United States, United Kingdom, Europe, and Australia, CHD is the dominant form of CVD. In others, both forms are co-dominant. In general, the early stages of the CVD epidemic are marked by haemorrhagic stroke and hypertensive heart disease as the major manifestations of high blood pressure. As societies move to high-fat diets and increased rates of smoking, thrombotic CVDs (CHD and thrombotic stroke) become prominent. In cancer too, there is considerable geographic variation in the types of cancers that are most frequent. This is related to variations in patterns of diet, tobacco consumption, alcohol use, and exposure to cancer-causing viruses.

Based on models of demographic and developmental transitions expected to occur over the coming two decades, the WHO estimates that the number of deaths attributable to NCDs would rise to 55 million by 2030, if urgent measures are not taken to contain the threat of these diseases. This will amount to 70 per cent of all global deaths that year. Action would be needed not only on timely diagnosis and treatment of manifest disease but, more importantly, on the prevention and control of risk factors before they result in disease.

NCDs also have an adverse impact on the economy, at national and global levels. This is due to the combined burden of healthcare costs and productivity losses resulting from deaths in working age and disease-related disability that curtails the ability to engage in fully productive work. A study conducted by the World Economic Forum and the Harvard School of Public Health estimated that the world would lose \$47 trillion, during 2011–2030, due to NCDs and mental illness (Bloom et al. 2011). About \$30 million of this would be due to CVD, cancers, diabetes, and chronic respiratory diseases. NCDs also result in catastrophic health expenditure and can push families into poverty because of unaffordable costs of technology-intensive medical care (Heeley et al. 2009).

Risk factors and determinants

Among the several risk factors associated with NCDs, three categories can be identified: biological, behavioural, and socio-economic. Of these, the four behavioural risk factors identified by the WHO (unhealthy diet, physical inactivity, tobacco consumption, and harmful use of alcohol) are positioned centrally. They are influenced upstream by socioeconomic determinants like education and income that operate at the individual level, and societal factors like trade policies, urban design and transport, media and cultural influences that operate at the population level. Behaviours in turn have a substantial impact on biological risk factors like blood pressure, body weight, body shape (central obesity), blood lipids, and blood sugar which are the downstream mediators of risk.

While the four behavioural risk factors are indeed the main contributors to NCDs, becoming the critical link between social determinants and biological causes, there are other risk factors

too which contribute to NCDs. These vary from viruses causing cancer, to indoor and outdoor air pollution causing respiratory diseases and CVDs. Family history plays a role too, but the focus of a public health strategy must be on modifiable risk factors.

The role that genetic factors play has not been sufficiently well defined to predict risk in many NCDs. Disorders like CHD and maturity-onset diabetes are polygenic and the variability explained by the identified genes so far is low. Study of gene-environmental interactions in NCDs suggests that the environment is the dominant determinant in the development of these conditions (Florez et al. 2006). However, genetic markers are more prominently associated with some cancers and help in risk prediction and targeted therapy. The role of epigenetics, wherein gene expression is altered by environmental exposures such as tobacco, diet, and chemical pollutants, is now coming to the fore. Similarly, the role of early life influences, of fetal and childhood nutrition and growth, is being invoked to explain adult susceptibility to NCDs (Barker et al. 2002). Further research in these areas may help to better identify population groups and individuals at a high risk of one or more of the NCDs.

The GBD 2010 supports this approach by revealing that the four major behavioural risk factors and high blood pressure account for the largest fraction of global deaths and disability (Lim et al. 2012). Global trends reveal that while tobacco consumption is declining in HICs, it is rising in LMICs. Similarly the population mean of systolic blood pressure has declined or stabilized in HICs but has risen and is now the highest in LMICs (Danaei et al. 2011). Overweight and obesity are continuing to rise in prevalence across all regions of the world. Diabetes too is escalating as a global epidemic, with LMICs dominating the league table of countries with the largest numbers of people with diabetes (International Diabetes Federation 2012).

Alongside the global transition, where NCD mortality rates are stabilizing or declining in HICs but rising in LMICs, there is also evidence of a progressive reversal of the social gradient as the epidemics mature. In the early stages of the NCD epidemics, harmful behaviours are more often associated with the higher disposable incomes of the rich, placing them in the high-risk category. However, as the epidemics advance, mediators of risk are mass produced for mass consumption and the ubiquitous presence of tobacco, alcohol, processed foods, labour saving devices, and motorized transport systems writes the prescription for mass epidemics. At a later stage, the affluent and educated sections benefit from their greater access to information, health services, healthy foods, and leisure time exercise to avoid or reduce the risk of NCDs. On the other hand, the poor and less educated sections have inadequate knowledge of NCDs and their risk factors, cannot afford regular purchase and consumption of fruit, vegetables, healthy oils, and fish, which are often costlier than unhealthy processed foods, and usually lead more stressful lives. In such a mature epidemic, the poor will be the most vulnerable victims and experience the highest burden of NCDs (Reddy et al. 2007). Across the world, different stages of this transition are evident in different regions, based on the level of economic and social development.

A comprehensive response

Health services are frequently confronted by the challenge of balancing a broad public health response focusing on the

determinants which operate at the population level and a medical response which places emphasis on providing clinical care to individuals with manifest disease or at a high risk of developing it. This challenge is often exacerbated by the limited resources available to the health system, especially in LMICs.

However, the strategic approach is best guided by understanding how 'risk' operates even in individuals, with respect to risk factors like elevated blood pressure or blood cholesterol or smoking. For example, abundant evidence, gathered from both observational epidemiology and clinical trials, enables us to state the following principles of risk for CVD:

1. Risk operates in a continuous manner, and not across arbitrary thresholds. This is true of biological variables like blood pressure, blood cholesterol, blood sugar, body mass index, and even to the number of cigarettes smoked per day.
2. Most adverse events arise in a population in people in the mid-range of a risk factor distribution—while high levels of any risk factor place individuals at higher relative risk, the majority of people in a population have risk factor levels in the mid-range and, therefore, contribute to the largest number of events.
3. When multiple risk factors coexist, the overall risk is additive.
4. In all populations, the majority of the CVD events arise in people with concurrent elevation of many risk factors rather than in individuals with a high level of a single risk factor.

Based on this, we can derive the principles of prevention:

1. Small reductions in risk factor levels, when achieved across the whole population, result in a large reduction of CVD events.
2. Non-drug measures prevent risk across the whole population and reduce it in people who have already acquired a high-risk profile.
3. Drug therapy to reduce risk is most cost-effective in people who are at high risk of adverse events in the next 10 years.
4. Best results are achieved through a combination of population-based prevention and high-risk individual management approaches.

For example, half of all blood pressure-related deaths occur below the clinical threshold of 140/90 mmHg which defines hypertension. Since the risk of CVD rises progressively at levels above 110/70 mmHg in adults, it is inconceivable that a majority of the population should be treated with drugs. Healthy diet, regular physical activity, and avoiding harm from alcohol can not only help individuals to lower blood pressure, but can shift the population distribution of blood pressure to the left, with a lower mean. This will substantially reduce the burden of CHD and stroke in that population. Among those with 'clinical hypertension', the combination of risk factors will determine the overall 'absolute risk' of CVD and define the threshold for intervention with drug therapy. For further discussion, see Chapter 8.1.

While these principles are derived from CVD epidemiology, they are also applicable to other NCDs where behavioural risk factors translate into biological risk. They would hold true for the relationship of body mass index, central obesity, and physical inactivity to diabetes or the relationship of air pollution to chronic respiratory diseases. Similarly, the risk of cancer with tobacco exposure has a continuous relationship. This makes a strong case

for population-based strategies to reduce risk exposure across a wide range, rather than focusing only on those at the highest level of exposure.

The fact that many biological risk factors are driven by a clustering of behaviours also provides the rationale for a strategy that focuses on the four behavioural risk factors identified by the WHO. Blood lipids, blood sugar, blood pressure, and obesity are influenced by diet, physical activity, and alcohol. Tobacco inter-actively amplifies the risk of each of these biological risk factors for NCDs. Action on these risk behaviours, therefore, will provide great benefits to populations as well as individuals by reducing the levels and effects of several biological risk factors.

In relation to the risk factors for NCDs, changing the behaviours of individuals is essential but is difficult and will take a concerted effort over a long time. More research is also required to ascertain the most effective ways in which this could be achieved, especially in the current global context where so much health-related information, and misinformation, is transmitted and shared through the Internet and social media networks, often on a peer-to-peer basis. It is critical, in parallel, to change environmental factors so as to create settings and environments that actively promote healthy behaviours and activities.

A comprehensive and integrated strategy should therefore encompass effective public health interventions to minimize risk factor exposure in the whole population and to reduce the risk of disease-related events in individuals at high risk. As this combination of the population approach and the high-risk approach is synergistically complementary, cost-effective, and sustainable, such an approach provides the strategic basis for early, medium-term, and long-term impact on NCDs.

The response to NCDs, therefore, requires concerted action at the level of policy, health systems, community action, and individual behaviours. Since the determinants of risk are driven by many social forces, including social inequalities that expose vulnerable segments of society to greater risks and reduced access to health promoting programmes, screening, and medical care, a comprehensive policy response is necessary, involving several sectors such as agriculture, food processing, urban design and transport, commerce, education, and communication. Tobacco control, for example, requires higher taxes on all tobacco products, a ban on tobacco advertising, effective health warnings, and smoke-free public and work places. Promotion of healthy diets would need availability of fruit, vegetables, and healthy oils at affordable prices and reduction of salt, sugar, and trans and saturated fats, in processed foods. Promotion of physical activity would require provision of safe pedestrian pathways, protected cycling lanes, community recreational facilities, green spaces, and mass transport systems that encourage walking to and from stations.

Health services must gear up capacity for early detection and treatment of NCDs and risk factors in primary healthcare, so that NCDs and their complications can be prevented and early therapy can be initiated when they do occur. At higher levels of care, more advanced diagnostic tests and treatments must become available at affordable cost.

Community level action, to promote good health and prevent disease, should involve schools, work sites, residential districts, associations of women, and young people. Apart from increasing health literacy, health-promoting environments must be created through smoke-free and exercise-friendly physical spaces,

cafeterias serving healthy food, and group activities that reduce stress and engender well-being. Individuals too must learn to exercise healthy choices related to tobacco, diet, physical activity, and alcohol.

The World Health Organization's global action plan

The UN meeting in 2011 identified a target of 25 per cent reduction in mortality due to NCDs, between the ages of 30 and 70 years, to be achieved globally by 2030. The World Health Assembly, in May 2013, approved a global action plan for prevention and control of NCDs, along with a set of voluntary targets and indicators linked to actions which will enable this goal to be achieved (WHO 2013).

This plan lists nine voluntary targets which are connected to 25 indicators (Table 11.2.1). To achieve these targets, WHO recommends the following actions.

Tobacco use

- ◆ Implement the Framework Convention on Tobacco Control (FCTC).
- ◆ Reduce affordability of tobacco products by increasing tobacco excise taxes.
- ◆ Create, by law, completely smoke-free environments in all indoor workplaces, public places, and public transport.
- ◆ Warn people of the dangers of tobacco and tobacco smoke through effective health warnings and mass media campaigns.
- ◆ Ban all forms of tobacco advertising, promotion, and sponsorship.

Harmful alcohol use

- ◆ Excise tax increases on alcoholic beverages.
- ◆ Comprehensive restrictions and bans on alcohol advertising and promotion.
- ◆ Restrictions on the availability of retailed alcohol.
- ◆ Implement the WHO global strategy to reduce harmful use of alcohol.

Unhealthy diet and physical inactivity

- ◆ Salt reduction through mass media campaigns/reduced salt content in processed foods.
- ◆ Replacement of trans fats with polyunsaturated fats.
- ◆ Public awareness programme about diet and physical activity.

Health system

- ◆ Integrate highly cost-effective NCD interventions into the basic primary healthcare package to advance the universal health coverage (UHC) agenda.
- ◆ Explore viable health financing mechanisms and innovative financing approaches, like tobacco and alcohol taxation, to generate resources to expand health coverage.
- ◆ Improve availability of affordable basic technologies and essential medicines, including generics, required to treat major NCDs in both public and private facilities.

Table 11.2.1 Voluntary global targets from the Action Plan for the Prevention and Control of Non-communicable Diseases 2013–2020

Mortality and morbidity		
1.	Premature mortality from non-communicable disease	A 25% relative reduction in risk of premature mortality from cardiovascular diseases, cancer, diabetes, or chronic respiratory diseases
Behavioural risk factors		
2.	Harmful use of alcohol	At least 10% relative reduction in the harmful use of alcohol, as appropriate, within the national context
3.	Physical inactivity	A 10% relative reduction in prevalence of insufficient physical inactivity
4.	Salt/sodium intake	A 30% relative reduction in mean population intake of salt/sodium
5.	Tobacco use	A 30% relative reduction in prevalence of current tobacco use in people aged 15+ years
Biological risk factors		
6.	Raised blood pressure	A 25% relative reduction in the prevalence of raised blood pressure or contain the prevalence of raised blood pressure, according to national circumstances
7.	Diabetes and obesity	Halt the rise in diabetes and obesity
National system response		
8.	Drug therapy to prevent heart attacks and strokes	At least 50% of eligible people receive drug therapy and counselling (including glycaemic control) to prevent heart attacks and strokes
9.	Essential non-communicable disease medicines and basic technologies to treat major non-communicable diseases	An 80% availability of the affordable basic technologies and essential medicines, including generics, required to treat major non-communicable diseases in both public and private facilities

Adapted with permission from World Health Organization, *Sixty Sixth World Health Assembly; Follow-up to the Political Declaration of the High-level Meeting of the General Assembly on the Prevention and Control of Non-communicable Diseases*, Copyright © World Health Organization 2013, available from http://apps.who.int/gb/ebwha/pdf_files/WHA66/A66_R10-en.pdf.

- ◆ Scale-up early detection and coverage starting with very cost-effective, high-impact interventions.
- ◆ Strengthen and reorient health systems to address NCDs and risk factors through people-centred primary healthcare and UHC.

Cardiovascular disease and diabetes

- ◆ Multidrug therapy (including glycaemic control for diabetes mellitus and control of hypertension through a total risk management approach) to individuals who have had a heart attack or stroke, and to people with high risk (≥ 30 per cent) of a fatal and non-fatal cardiovascular event in the next 10 years.
- ◆ Acetylsalicylic acid for acute myocardial infarction.
- ◆ Multidrug therapy (including glycaemic control for diabetes mellitus and control of hypertension through total risk approach) to individuals who have had a heart attack or stroke, and to people with moderate risk (≥ 20 per cent) of a fatal and non-fatal cardiovascular event in the next 10 years.
- ◆ Acetylsalicylic acid, atenolol, and thrombolytic therapy (e.g. streptokinase) for acute myocardial infarction.
- ◆ Treat congestive cardiac failure with an angiotensin-converting enzyme inhibitor, beta-blocker, and diuretic.
- ◆ Cardiac rehabilitation post myocardial infarction.
- ◆ Secondary prevention of rheumatic fever and rheumatic heart disease.
- ◆ Anticoagulation for medium- and high-risk non-valvular atrial fibrillation and for mitral stenosis and atrial fibrillation.
- ◆ Low-dose acetylsalicylic acid for ischaemic stroke.
- ◆ Care of acute stroke and rehabilitation in stroke units.
- ◆ Interventions for foot care; educational programmes, access to appropriate footwear; and multidisciplinary clinics.

Diabetes

- ◆ Lifestyle interventions for preventing type 2 diabetes.
- ◆ Influenza vaccination.
- ◆ Preconception care among women of reproductive age (includes patient education and intensive glucose management for gestational diabetes).
- ◆ The early detection of diabetic retinopathy by regular dilated eye examination followed by appropriate laser photocoagulation therapy to prevent blindness.
- ◆ Enalapril to prevent progression of renal disease.

Cancer

- ◆ Prevention of liver cancer through hepatitis B immunization.
- ◆ Prevention of cervical cancer through screening (visual inspection with acetic acid) linked with timely treatment of pre-cancerous lesions.
- ◆ Vaccination against human papillomavirus, as appropriate if cost-effective and affordable, according to national programmes and policies.
- ◆ Population-based cervical cancer screening linked with timely treatment.
- ◆ Population-based breast cancer mammography screening (50–70 years) linked with timely treatment.

- ◆ Population-based colorectal cancer screening at ages over 50 years, linked with timely treatment.
- ◆ Oral cancer screening in high-risk groups (e.g. tobacco users) linked with timely treatment.
- ◆ Palliative care; using cost-effective treatment modalities including opioid analgesics for pain relief.

Chronic respiratory disease

- ◆ Access to improved stoves and cleaner fuels to reduce indoor air pollution.
- ◆ Cost-effective interventions to prevent occupational lung diseases, that is, exposure to silica, asbestos.
- ◆ Treatment of asthma based on WHO guidelines.
- ◆ Influenza vaccination for patients with chronic obstructive pulmonary disease.

Research and surveillance

- ◆ Develop and implement a prioritized national research agenda for NCDs.
- ◆ Strengthen research capacity through cooperation with research institutes.
- ◆ Implement other policy options to promote and support national capacity for high-quality research and development.
- ◆ Develop national targets and indicators based on global monitoring framework.
- ◆ Establish/strengthen a comprehensive NCD surveillance system, including reliable registration of deaths by cause, cancer registration, periodic data collection on risk factors, and monitoring national response.
- ◆ Integrate NCD surveillance/monitoring into national health information systems.
- ◆ Monitor trends and determinants of NCDs and evaluate progress in their prevention and control.

These recommendations for national and global actions are based on evidence of high impact on population-attributable risk and cost-effectiveness of the interventions (Beaglehole et al. 2011; WHO 2011d; Bonita et al. 2013). They combine policy and community level interventions which impact on behaviours across the population and health service interventions which enable risk reduction in individuals at high risk of NCD-related death or disability. While many of these are steered by the health system, they will require multi-sectoral actions to influence the determinants of NCDs. Together, they provide a comprehensive framework for prevention and control of NCDs.

Health system challenges

Implementation of the various measures proposed in the WHO's Global NCD Action Plan (as discussed earlier) will pose several challenges to national health systems, especially those in the LMICs. These include: health financing; human resources for health; access to essential drugs and technologies and information systems, apart from infrastructure and governance.

Even as escalating costs of healthcare are straining health systems across the world, there is the imminent danger of the

expanding NCD epidemics loading unaffordable costs on health budgets. Most LMICs have to contend with competing priorities, with continued commitment to funding programmes for maternal and child health, control of infectious diseases, and nutrition along with fresh commitments to programmes for NCD prevention and control. It should be noted that some key policy measures such as for the control of tobacco and alcohol use will not demand many resources.

Indeed, higher taxes on tobacco and alcohol will yield additional revenues which can be allocated to NCD-related health programmes. Each measure like downward regulation of salt, sugar, and saturated and trans fats in processed foods would not incur expenditure for the government.

However, programmes for clinical care will entail substantial additional costs to the health budget. This can be contained by integrating NCD prevention into existing health programmes (like tobacco control, maternal and child health, and HIV/AIDS programmes) and investing more in primary care than in tertiary care.

As many countries move towards implementation of UHC, NCD-related services should be included so that essential health-care is provided in an accessible, affordable, and equitable manner to all who need it. The growing global momentum for UHC coincides with the increasing recognition of NCDs as a major health priority, indicative of a convergence that accommodates NCDs in UHC (Frenk and de Ferranti 2012).

Most LMICs have severe shortages in their healthcare workforce, at various levels (specialist doctors, primary physicians, nurses, allied health professionals, and community health workers). Even as capacity is progressively scaled up at each of these levels, 'task shifting' and 'task sharing' can enhance the outreach and effectiveness of NCD programme delivery. Non-physician healthcare providers like nurses and community health workers have been shown to detect and manage diabetes, hypertension, and asthma efficiently with good health outcomes (Coleman et al. 1998; Abegunde et al. 2007; Farzadfar et al. 2012). Health workers in different health programmes can be multiskilled to perform some functions related to NCD prevention and control, in addition to their primary functions. Specific programmes for NCD prevention and control would also need a multilayered work force with competencies attuned to the programme. Training programmes need to be developed for this purpose. Public health education too must be strengthened to increase public health expertise for policy and programme design, delivery, and evaluation.

Provision of essential drugs and access to needed technologies are also priorities which the health system must address. Since NCDs usually require long-term and often lifelong care for chronic conditions, the availability and affordability of drugs becomes a major concern to affected individuals and families. This is true of drugs for the treatment of hypertension and diabetes, where the cost of drugs in several LMICs amounts to a large fraction of the average monthly wage (Van Mourik et al. 2010). With respect to cancer, treatment for curable cancers is often out of reach, because of the prohibitive cost of drugs. In several countries, palliative pain-relief therapy is unavailable to cancer patients. Even inhalers for asthma therapy are not universally available.

There is a great need for increasing the production and availability of generic drugs. Countries with high manufacturing capacity for such drugs (such as China, India, and Brazil) must supply not

only their domestic markets but also other needy markets. Pooled procurement, at national and global levels, will help keep costs under control. The WHO is examining mechanisms for such global procurement and distribution of essential NCD-related drugs. At the national level, it must ensure that frequently needed NCD drugs of proven efficacy should be entered into the Essential Drug List (EDL). Measures to ensure affordability and access, including price control and public provision of life-saving cancer drugs, should also be considered by governments.

Access to technologies is also vital for NCD prevention and control. While high-cost technologies should be judiciously used, based on rational guidelines, low-cost technologies can greatly advance primary care. Point-of-care diagnostics need to be promoted, to enable early detection of risk factors. Use of information technology and mobile phones offer a potentially powerful health system innovation that can transform primary care for NCDs (Krishna et al. 2009). They can also help in strengthening surveillance systems, enabling programme managers to acquire real-time data from sentinel sites across the country and provide a rapid response.

Health services too must be reconfigured to provide chronic care and emergency care for NCDs. Presently, the health systems of most LMICs are designed to deliver acute episodic care, rather than continuous care involving periodic reviews and monitoring. Integration of primary with secondary and tertiary services, with clearly defined and dependable systems for bi-directional referral and follow-up, is also a requirement of NCD-related care. Emergency care services too need to be geared up, to save lives through early intervention in cases of acute coronary or cerebrovascular events.

Conclusion

Prevention and control of NCDs will be the dominant health challenge of the twenty-first century. While it would be unrealistic to expect that all NCDs can be prevented, a large fraction of them can be prevented from occurring or affecting people in young and middle ages. Prevention of premature mortality and reduction of NCD-related morbidity and disability are goals that every national health system must pursue and all global partnerships must support. That these are achievable has been demonstrated in many HICs. Success does not derive only from costly clinical care. Prevention, through policies which create conducive environments in which people can make and maintain healthy living choices without formidable barriers, has contributed to most of the decline in NCDs that has been observed in HICs. Tobacco control is a prime example of how NCD mortality rates decline in response to policy and community-led initiatives (Unal et al. 2004). Countries like Finland and Poland have demonstrated how policies and community-based programmes influencing dietary choices can put brakes on the CVD epidemic (Zatonski and Willett 2005; Puska 2013).

The decline of cervical cancer, with organized screening and treatment (Mathew and George 2009), and the decline in lung cancer mortality, due to falling smoking rates in HICs, offer lessons for LMICs. It has also been observed that risk factor reduction explains 44–76 per cent of declining mortality in the United States, with improvements in clinical care contributing to the rest (Ford and Capewell 2011). LMICs can learn from the global

experience of countries which have already experienced the NCD epidemics in full tide. At the same time, they will have to prioritize prevention and primary care over high-cost tertiary and terminal care, if their health systems are to successfully cope with the demands of multiple health burdens in a resource-constrained situation. Fortunately, knowledge related to effective prevention and lifesaving clinical care is available. It is now time to translate that abundant knowledge into effective action, if the ambitious but achievable goal of ‘25 by 25’ is to be realized.

Principles of infectious disease control

Robert J. Kim-Farley

Principles of infectious disease control: overview

Infectious diseases remain a leading cause of morbidity, disability, and mortality worldwide. Lower respiratory infections are the third leading causes of death worldwide (World Health Organization (WHO) 2008). Their control is a constant challenge that faces health workers and public health officials in both industrialized and developing countries. Only one infectious disease, smallpox, was eradicated and stands as a landmark in the history of the control of infectious diseases. The international community is now well down the path towards eradication of poliomyelitis and dracunculiasis (Guinea worm infection). Other infectious diseases, like malaria and tuberculosis, foiled eradication attempts or control efforts and are re-emerging as increasing threats in many countries, including both developing and developed countries. Some infectious diseases, such as tetanus, will always be a threat if control measures are not maintained. Newer infectious diseases, like AIDS, demonstrate the truth of McNeill's statement that infectious disease will remain 'one of the fundamental parameters and determinants of human history'. The history of infectious diseases is an exciting story in itself and readers interested in the subject are referred to McNeill (1976) or the comprehensive work on the history of human diseases (Kiple 1993).

This chapter provides a global and comprehensive view of infectious disease control through examination of the magnitude of disease burden, the chain of infection (agent, transmission, and host) of infectious diseases, the varied approaches to their prevention and control, and the factors conducive to their eradication as well as emergence and re-emergence. Although this chapter provides many examples of infectious diseases that illustrate modes of transmission and approaches to infectious disease control, this chapter does not attempt to be comprehensive in listing all infectious diseases. Detailed recommendations on control measures for any specific disease are outlined periodically in the updated reports of the American Public Health Association, *Control of Communicable Diseases Manual* (Heymann 2010), the comprehensive two-volume work *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases* (Mandell et al. 2009), and the textbook *Infectious Diseases* (Gorbach et al. 2004). For readers specifically interested in paediatric infectious diseases there is the comprehensive two-volume *Feigin and Cherry's Textbook of Pediatric Infectious Diseases* (Feigin et al. 2009); for

infectious diseases in emergency medicine settings there is the textbook *Infectious Diseases: Emergency Department Diagnosis & Management* (Red and White Emergency Medicine Series) (Slaven et al. 2006); and for tropical infectious diseases there is *Tropical Infectious Diseases: Principles, Pathogens, and Practice* (Guerrant et al. 2011). A comprehensive treatment of the worldwide distribution of infectious diseases is provided in *Atlas of Human Infectious Diseases* (Wertheim et al. 2012). The Centers for Disease Control and Prevention (CDC) publishes up-to-date disease surveillance information for the United States and recommendations for control measures in the *Morbidity and Mortality Weekly Reports* and provides annual summaries of notifiable infectious diseases in the *Summary of Notifiable Diseases, United States* (CDC 2011). Many other countries have similar types of publications. The WHO publishes worldwide surveillance information and recommendations for control measures in the *Weekly Epidemiological Record*. A more detailed background on infectious agents as determinants of health and disease is provided in Chapters 8.11–8.15.

Definitions of infectious diseases and their control

Infection occurs when an infectious agent enters a body and develops or multiplies. *Infectious agents* are organisms capable of producing inapparent infection or clinically manifest disease and include bacteria, rickettsia, chlamydiae, fungi, parasites, viruses, and prions. An *infectious disease*, or communicable disease, is an infection that results in clinically manifest disease. Infectious disease may also be due to the toxic product of an infectious agent, such as the toxin produced by *Clostridium botulinum* causing classical botulism. As this is a textbook of public health, the infectious diseases considered are those that manifest in human hosts and are a result of the interaction of people, animals, and their environment. Infectious diseases may be due to infectious agents exclusively found in human hosts such as rubella virus, in the environment such as *Legionella pneumophila*, or primarily in animals such as *Brucella abortus*.

Control of infectious diseases refers to the actions and programmes directed towards reducing disease incidence (new infections), reducing disease prevalence (infections in the community at any given point in time), or completely eradicating the disease. Control aimed at reducing the incidence of infectious disease or their risk factors can be considered as *primary prevention* of infectious disease. Primary prevention protects health through individual and community-wide measures, including such actions

as maintaining good nutritional status, keeping physically fit, immunizing against infectious diseases, providing safe water, and ensuring the proper disposal of faeces.

Control aimed at reducing the prevalence by shortening the duration of infectious disease can be considered as *secondary prevention* of infectious disease. Secondary prevention corrects departures from good health through individual and community-wide measures, including such actions as screening that result in early detection of disease, prompt antibiotic treatment, and ensuring adequate nutrition. It should be noted that such control efforts in secondary prevention in a group of infected individuals may also result in primary prevention in uninfected people. For example, prompt and specific drug therapy for tuberculosis patients resulting in sputum conversion to culture-negative status renders them no longer a source of infection to others and treatment of HIV-positive pregnant women reduces transmission of HIV to their newborns.

Control aimed at reducing or even eliminating long-term impairments of infectious disease can be considered as *tertiary prevention* of infectious disease. Tertiary prevention reduces or eliminates disabilities, minimizes suffering, and promotes adjustment to permanent disabilities through such actions as providing orthopaedic appliances and its associated rehabilitation for victims of poliomyelitis, counselling and vocational training, and prevention of opportunistic infections. For example, the prevention of opportunistic infections in HIV infection can be considered as tertiary prevention (Osterholm and Hedberg 2005).

Global burden of infectious diseases

A WHO analysis of the global burden of disease estimates that infectious diseases caused 12.3 million deaths, accounting for 21 per cent of total global mortality of 56.8 million deaths in 2008 (WHO 2008). Five diseases—lower respiratory infections, AIDS, diarrhoeal diseases, tuberculosis, and malaria—account for some 81 per cent of the total infectious disease burden. Most infectious disease (some 97 per cent) deaths occur in the economically developing group of countries where approximately a quarter of deaths are due to an infectious cause (WHO 2008). However, infectious diseases are also of importance in more developed countries. In the United States, for example, influenza still ranks as an important cause of death.

The current magnitude of morbidity and mortality due to infectious diseases worldwide is highlighted by the WHO as follows (WHO 2012a):

- ◆ *Acute lower respiratory infections*, including pneumonia and influenza, cause some 447 million episodes of illness each year and result in 3.5 million deaths annually. These infections are the highest cause of infant and child mortality in developing countries.
- ◆ *HIV* newly infects about 2.7 million people each year and causes an estimated 1.8 million AIDS-related deaths annually, down from a peak of 2.2 million that occurred in the mid 2000s. There are now about 34 million people living with HIV as of the end of 2011 (Joint United Nations Programme on HIV/AIDS 2011).
- ◆ *Diarrhoeal diseases* are also a major cause of morbidity and mortality in infants and children in developing countries. Each year there are some 4.6 billion episodes with 2.5 million deaths

due to diarrhoeal disease, of which the vast majority are among children under 5 years of age.

- ◆ *Tuberculosis*, caused by *Mycobacterium tuberculosis*, infects about one-third of the world's population. It is estimated that there are approximately 8.8 million people who develop clinical disease and 1.1 million who die of tuberculosis each year.
- ◆ *Malaria* is estimated to cause some 241 million cases of acute illness. An estimated 827,000 deaths per year worldwide are attributable to malaria, mainly in children under the age of 5 years.
- ◆ *Influenza* epidemics, caused by influenza A and B viruses, are estimated to kill from 500,000 to 1 million people worldwide each year. Influenza pandemics, of which there were 3 in the last century, have killed as many as 40–50 million people (as occurred during the 1918–1919 'Spanish flu' pandemic) and, as with the current concerns regarding avian influenza (H5N1), continue to threaten to re-emerge as a major public health emergency.

Chain of infection: agent, transmission, and host

The chain of infection is the relationship between an infectious agent, its routes of transmission, and a susceptible host. The prevention and control of infectious diseases depend upon the interaction of these three factors that may result in the human host clinically manifesting disease.

Agent

The infectious agent is the first link in the chain of infection and is any microorganism whose presence or excessive presence is essential for the occurrence of an infectious disease. Examples of infectious agents include the following:

- ◆ *Bacteria*: for example, spirochetes and curved bacteria such as *Borrelia burgdorferi* causing Lyme disease; Gram-negative rods such as *Yersinia pestis* causing plague; Gram-positive cocci such as *Streptococcus pyogenes*, group A causing erysipelas; and Gram-positive rods such as *Mycobacterium tuberculosis* causing tuberculosis.
- ◆ *Rickettsiae*: for example, *Rickettsia rickettsii* causing Rocky Mountain spotted fever, and *Rickettsia prowazekii* causing epidemic louse-borne typhus fever.
- ◆ *Chlamydiae*: for example, *Chlamydia psittaci* causing psittacosis (ornithosis), and *Chlamydia trachomatis* causing trachoma and genital infections.
- ◆ *Fungi*: for example, *Trichophyton schoenleinii* and *Microsporum canis* causing tinea capitis (ringworm of the scalp), and *Trichophyton rubrum*, *Trichophyton mentagrophytes*, and *Epidermophyton floccosum* causing tinea pedis (ringworm of the foot, or athlete's foot).
- ◆ *Parasites*: for example, helminths such as *Trichinella spiralis* causing trichinosis, filaria such as *Brugia malayi* causing filariasis (which may lead to the symptom of elephantiasis), nematodes such as *Enterobius vermicularis* causing enterobiasis (pinworm disease), trematodes such as *Clonorchis sinensis* causing clonorchiasis (oriental liver fluke disease), cestodes such as *Taenia*

solium causing taeniasis (beef tapeworm disease), and protozoa such as *Trypanosoma cruzi* causing American trypanosomiasis (Chagas' disease).

- ♦ **Viruses:** for example, Paramyxoviridae such as measles virus which causes measles, Togaviridae such as rubella virus which causes rubella, Picornaviridae such as the hepatovirus which causes hepatitis A, and arthropod-borne viruses (arboviruses) such as dengue viruses which cause dengue fever.
- ♦ **Prions:** small proteinaceous infectious particles which cause such diseases as kuru, Creutzfeldt–Jakob disease (and its variant associated with exposure of humans to the bovine spongiform encephalopathy, or 'mad cow', agent), and the Gerstmann–Straussler–Scheinker syndrome.

There is increasing evidence that some infectious agents, often with cofactors, are associated with human tumours. Examples include: *Schistosoma haematobium* with bladder cancer, *Schistosoma japonicum* with colorectal cancer, *Clonorchis sinensis* with cholangiocarcinoma, hepatitis B and C viruses with hepatocellular carcinoma, *Helicobacter pylori* with gastric cancer, and human papillomaviruses with cervical cancer. Cancers attributed by the International Agency for Research on Cancer (IARC) to infectious agents are considered to account for some 22 per cent of cancer deaths in the developing world and 6 per cent in industrialized countries (WHO 2003).

Agents can be described by their ability to infect (infectivity), be transmitted (infectiousness), and cause disease (pathogenicity) as well as their ability to cause serious disease (virulence). The *infectivity* of an infectious agent is the extent to which the agent can enter, survive, and multiply in a host and is measured by the ratio of the number of people who become infected to the total number exposed to the agent. Rhinoviruses that can cause the common cold are examples of infectious agents with high infectivity.

The *infectiousness*, or transmissibility, of an infectious agent is the extent to which the agent can be transmitted from one host to another. It is measured by the basic reproduction number (known as R_0) which is determined by the number of secondary infections in a susceptible population that result from a primary infection. Epidemic-prone diseases such as measles and pertussis caused by measles virus and *Bordetella pertussis* bacteria, respectively, are examples of diseases due to highly infectious agents with an R_0 of 10 or greater.

The *pathogenicity* of an infectious agent is the extent to which clinically manifest disease is produced in an infected population and is measured by the ratio of the number of people developing clinical illness to the total number infected. Examples of highly pathogenic infectious agents are the measles virus and the human (α) herpesvirus 3 (varicella-zoster) causing measles and chickenpox, respectively, in which most infected susceptible people will manifest disease.

The *virulence* of an infectious agent is the extent to which severe disease is produced in a population with clinically manifest disease. It is the ratio of the number of people with severe and fatal disease to the total number of people with disease. An example of a highly virulent infectious agent is HIV whereby nearly all untreated people with AIDS will die.

Characteristics of infectious agents that affect pathogenicity include their ability to invade tissues (invasiveness), produce

toxins (intoxication), cause damaging hypersensitivity (allergic) reactions, undergo antigenic variation, and develop antibiotic resistance. An example of an infectious agent with high *invasiveness* is the *Shigella* organism which can invade the submucosal tissue of the intestine and cause clinically manifest shigellosis (bacillary dysentery). An example of an infectious agent that has a high degree of ability to *produce toxins* is the *Clostridium botulinum* organism which can elaborate toxins in inadequately prepared food and cause classical botulism. An example of an infectious agent that is highly *allergenic* is the *Mycobacterium tuberculosis* organism which can cause tuberculosis. An example of an infectious agent that has a high degree of *antigenic variation* is the type A influenza virus which frequently experiences minor antigenic changes—antigenic 'drift'. Influenza A viruses, on an irregular basis, may also undergo a major antigenic change creating an entirely new subtype—antigenic 'shift'. Antigenic shifts that have the characteristic of high transmissibility between people may result in an influenza pandemic when large numbers of individuals are exposed to the new subtype for which they have no prior immunity. An example of an infectious agent that can develop *antibiotic resistance* that challenges control efforts is *Neisseria gonorrhoeae* that has both chromosomally mediated and resistance transfer plasmid-mediated genetic factors for antibiotic resistance.

The *infective dose* of an infectious agent is the number of organisms needed to cause an infection. The infective dose may vary depending upon the route of transmission and host susceptibility. An example of an infectious agent that needs only a very low infective dose (as few as ten organisms) is *Escherichia coli* O157:H7 which causes enterohaemorrhagic diarrhoea. An example of an infectious agent that needs a relatively higher infective dose is *Vibrio cholerae* which requires around 100 million bacteria to be ingested to cause cholera disease in a healthy adult.

Control measures for infectious diseases directed at inactivating the agent are designed according to the type of agent and its reservoirs and sources. For example, an agent like *Vibrio cholerae* can be inactivated through adequate chlorination of the water supply. This is a chemical method for provision of safe water to control cholera. An agent like hepatitis B virus can be inactivated through adequate autoclaving of injection and surgical equipment. This is a sterilization method to control hepatitis B. Details of these and other methods of control directed at the agent are provided in the sections in this chapter on control measures applied to the agent and the environment.

Routes of transmission

Control efforts are often designed to break the routes of transmission, the mechanisms by which infectious agents are spread from reservoirs or sources to human hosts. A *reservoir* of an infectious agent is any person, other living organism, or inanimate material in which the infectious agent normally lives and grows. The *source* of infection for a host is the person, other living organism or inanimate material from which the infectious agent came. *Horizontal transmission* refers to transmission between individuals whereas *vertical transmission* refers to the specific situation of transmission between parent to offspring (e.g. transplacentally *in utero*, during passage through the birth canal, or through breast milk). The routes of transmission have

been summarized in the *Control of Communicable Diseases Manual* (Heymann 2010) as follows:

Direct transmission

Direct and essentially immediate transfer of infectious agents to a receptive portal of entry through which human or animal infection may take place. This may be by direct contact such as touching, biting, kissing or sexual intercourse, or through direct projections (droplet spread) of droplet spray onto the conjunctiva or onto the mucous membranes of the eye, nose or mouth during sneezing, coughing, spitting, singing or talking (risk of transmission in this manner is usually limited to a distance of about 1 meter or less from the source of infection). Direct transmission may also occur through direct exposure of susceptible tissue to an agent in soil, through the bite of a rabid animal, or trans-placentally. (Heymann 2010)

Indirect transmission

Vehicle-borne

Contaminated inanimate materials or objects (fomites) such as toys, handkerchiefs, soiled clothes, bedding, cooking or eating utensils, surgical instruments or dressings; water, food, milk, and biological products including blood, serum, plasma, tissues or organs; or any substance serving as an intermediate means by which an infectious agent is transported and introduced into a susceptible host through a suitable portal of entry. The agent may or may not have multiplied or developed in or on the vehicle before being transmitted. (Heymann 2010)

Vector-borne

Mechanical: includes simple mechanical carriage by a crawling or flying insect through soiling of its feet or proboscis, or by passage of organisms through its gastrointestinal tract. This does not require multiplication or development of the organism.

Biological: propagation (multiplication), cyclic development, or a combination of these (cyclopropagative) is required before the arthropod can transmit the infective form of the agent to humans. An incubation period (extrinsic) is required following infection before the arthropod becomes infective. The infectious agent may be passed vertically to succeeding generations (*transovarian transmission*); *trans-stadial transmission* indicates its passage from one stage of the life cycle to another, as from nymph to adult. Transmission may be by injection of salivary gland fluid during biting, or by regurgitation or deposition on the skin of feces or other material capable of penetrating through the bite wound or through an area of trauma, often created by scratching or rubbing. This transmission is by an infected nonvertebrate host and not simple mechanical carriage by a vector as a vehicle. An arthropod in either role is termed a vector. (Heymann 2010)

Airborne transmission

The dissemination of microbial aerosols to a suitable portal of entry, usually the respiratory tract. Microbial aerosols are suspensions of particles in the air consisting partially or wholly of microorganisms. They may remain suspended in the air for long periods of time, some retaining and others losing infectivity or virulence. Particles in the 1- to 5-micrometer range are easily drawn into the alveoli of the lungs and may be retained there. Not considered as airborne are droplets and other large particles that promptly settle out (see 'Direct transmission').

Droplet nuclei: usually the small residues that result from evaporation of fluid from droplets emitted by an infected host (see above). They also may be created purposely by a variety of atomizing devices, or accidentally as in microbiology laboratories, abattoirs, rendering plants or autopsy rooms. They usually remain suspended in the air for long periods.

Dust: the small particles of widely varying size that may arise from soil (e.g., fungus spores), clothes, bedding, or contaminated floors. (Heymann 2010)

Control measures for infectious diseases directed at interrupting transmission are designed according to the type of transmission for the agent. Direct transmission of an agent like *Neisseria gonorrhoeae*, for example, can be reduced by using condoms as a barrier method of control of gonorrhoea. Vector-borne transmission of an agent like *Plasmodium falciparum* can be reduced by using a residual insecticide against *Anopheles* mosquitoes as a chemical vector control method for malaria. Airborne transmission of an agent like *Mycobacterium tuberculosis* from sputum-positive pulmonary tuberculosis patients in hospital can be reduced by the use of special ventilation in the patient's room as an environmental method of control of tuberculosis. It should be recognized that some infectious agents may have more than one route of transmission. Poliovirus, for example, can be spread via direct transmission through the faecal–oral route and pharyngeal spread, or indirect transmission through contaminated food or other materials. Details of these and other methods of control directed at interrupting transmission are provided in the section on 'Tools for control of infectious diseases' in this chapter.

Host

The human host is the final link in the chain of infection. The infectious agent may enter the host through the following portals of entry.

- ◆ *Respiratory tract*: infectious agents can be inhaled into the respiratory tract and will be deposited at different levels of the pulmonary tree according to the size of the aerosol, droplet nuclei, or dust particles. For example, *Mycobacterium tuberculosis* in airborne droplet nuclei, 1–5 µm in diameter, may be inhaled into the alveoli of the lungs of a vulnerable host and result in tuberculosis.
- ◆ *Intact skin*: some infectious agents, such as *Necator americanus* which causes hookworm disease, can penetrate the intact skin.
- ◆ *Gastrointestinal tract*: an infectious agent, such as *Vibrio cholerae* which causes cholera, may enter via the gastrointestinal tract. People who have a compromised gastric function, such as gastric achlorhydria, may be at increased risk of disease.
- ◆ *Mucous membranes*: infectious agents, such as measles viruses, may be deposited on mucous membranes, including the conjunctiva of the eye, by droplet spread or by direct contact with infected people or contaminated objects.
- ◆ *Genitourinary system*: some infectious agents, such as *Escherichia coli* which causes urinary tract infections, can enter the urinary tract via an ascending route from the urethra colonized with the organism. Structural abnormalities of the urinary tract and procedures such as urinary catheterization may predispose the host to disease. Sexually transmitted infectious agents, such as *Neisseria gonorrhoeae* which causes gonorrhoea, may enter the male or female genital orifices.
- ◆ *Placenta*: certain infectious agents, such as rubella virus which causes congenital rubella syndrome, can cross the placenta resulting in transplacental transmission, a direct route of transmission from the mother to the fetus that is a form of vertical transmission.

Infectious agents also enter the host through *mechanisms that get past the body's natural barriers*, including wounds that break the

integrity of the skin or mucous membranes; invasive procedures, parenteral injections, parenteral infusions, blood transfusions, or organ transplants that may introduce an agent into the body; or insect vectors that may inject agents through the skin.

The most important *host factors* regarding developing clinically manifest disease and the severity of disease are immune status and age. Infants, young children, and the elderly are at generally higher risk from more severe disease due to immaturity or deterioration of their immune systems, respectively. Host co-infections or other health conditions that diminish the immune status, for example, HIV infection or malnutrition, respectively, are also risk factors.

Many *host defence mechanisms* help prevent infection or disease. *Non-specific* host defence mechanisms include the intact skin (by providing a natural barrier), sinus and nasal cilia (by moving mucus and particles towards the nasal cavity), tears, saliva, and mucus (by preventing drying and containing lysozymes and other components with antimicrobial properties), and gastric acid (by the antimicrobial and antiparasitic properties of hydrochloric acid). *Specific* host defence mechanisms include naturally acquired immunity from previous infection, transplacentally acquired passive immunity in the newborn from the mother, artificially acquired active immunity from immunization, and artificially acquired passive immunity from immunoglobulins and antitoxins.

Host responses to infection that prevent or reduce the severity of infectious disease include: (1) polymorphonuclear leucocytosis stimulated by some bacterial infections that increases the number of phagocytic white blood cells, (2) fever that may slow the multiplication of some infectious agents, (3) antibody production that may neutralize some infectious agents or their toxins, (4) interferon production that may block intracellular replication of viruses, and (5) cytotoxic immune cell responses that kill cells infected with viruses.

The *manifestation of infection* in the host may vary from inapparent (subclinical) infection to severe disease that may even result in death. The interaction between an infectious agent, routes of transmission, and host factors determines the spectrum of signs and symptoms. Sometimes the host may become an asymptomatic carrier of the infectious agent and be a source of infection for others.

Control measures for infectious diseases directed at the host are designed according to the immune status of the host and the likelihood of host exposure to certain infectious agents. For example, measles disease can be prevented by active immunization with measles vaccine to develop host immunity. Pneumonic plague can be prevented in those in close contact with patients with plague pneumonia by chemoprophylaxis using tetracycline or sulphonamide. Details of these and other methods of control directed at the host are provided in the section on control measures applied to the host in this chapter.

Tools for control of infectious diseases

The primary concern of infectious disease control in public health, whether in developing or industrialized countries, is the reduction, elimination, or even eradication of infectious disease. This is accomplished by directing control measures to the agent, the routes of transmission, or the host. Such control measures include: (1) identifying and then reducing or eliminating

infectious agents at their sources and reservoirs, (2) breaking or interfering with the routes of transmission of infectious agents, and (3) identifying susceptible populations and then reducing or eliminating their susceptibility.

The tools for control of infectious diseases are related to recognition and evaluation of the patterns of diseases and the results of interventions to control them. In infectious disease control, the most important tool for recognition and evaluation is *surveillance* of disease defined as:

the process of systematic collection, orderly consolidation and analysis, and evaluation of pertinent data with prompt dissemination of the results to those who need to know them, and particularly those who are in a position to take action. It includes the systematic collection and evaluation of:

1. Morbidity and mortality reports
2. Special reports of field investigations of epidemics and of individual cases
3. Isolation and identification of infectious agents by laboratories
4. Data concerning the availability, use and untoward effects of vaccines and toxoids, immune globulins, insecticides and other substances used in control
5. Information regarding immunity levels in segments of the population
6. Other relevant epidemiologic data

A report summarizing the above data should be prepared and distributed to all cooperating persons and others with a need to know the results of the surveillance activities. The procedure applies to all jurisdictional levels of public health from local to international. (Heymann 2010)

Surveillance, therefore, is 'information for action'. More detailed information on surveillance or on field investigations is given in Chapter 5.19.

Tools for control related to *interventions* include:

- ◆ *Control measures applied to the host:* active immunization, passive immunization, chemoprophylaxis, behavioural change, reverse isolation, barriers, and improving host resistance.
- ◆ *Control measures applied to vectors:* chemical, environmental, and biological.
- ◆ *Control measures applied to infected humans:* chemotherapy, isolation, quarantine, restriction of activities, and behavioural change.
- ◆ *Control measures applied to animals:* active immunization, isolation, quarantine, restriction or reduction, chemoprophylaxis, and chemotherapy.
- ◆ *Control measures applied to the environment:* provision of safe water, proper disposal of faeces, food and milk sanitation, and design of facilities and equipment.
- ◆ *Control measures applied to infectious agents:* cleaning, cooling, pasteurization, disinfection, and sterilization.

Achieving maximum impact on control of a specific infectious disease may involve more than one of these interventions. For example, the control of hepatitis A infection can be achieved through interventions that may include: active immunization, passive immunization, food preparation and hand-washing behaviours, provision of safe water, food sanitation, and proper disposal of faeces.

The tools for control can also be considered according to the level at which they are applied: individual, institutional, or community

based. At the *individual level*, control measures, usually initiated by a clinician, are directed towards the specific infectious disease threats to the particular individual. Examples include chemoprophylaxis to prevent wound infection, pre-exposure prophylactic immunization against rabies for a veterinarian, and use of diphtheria antitoxin in a patient with diphtheria.

At the *institutional level*, control measures, usually initiated by the officials of the institution, are directed to a group of people who are in close contact with each other, such as people in day-care centres, schools, military barracks, hospital wards, nursing homes, and correctional facilities. Examples include: (1) administering amantadine hydrochloride or rimantadine for chemoprophylaxis or chemotherapy of influenza A in a high-risk institutional population, (2) quarantining institutionalized young children during a measles outbreak, and (3) hepatitis B immunization of staff and clients of institutions for the developmentally disabled.

At the *community level*, control measures, usually initiated by local, state or national public health agencies, are directed to the community at large. Examples include childhood immunization programmes, provision of safe water, regulation of food supplies, and recall of contaminated food products.

It should be noted that some control measures, such as immunization, may take place at all levels while others, such as the provision of safe water to a community, are more specifically applied at a particular level.

The tools for the control of infectious diseases and their relationship to the chain of infection are the main focus of the remainder of this chapter.

Control measures applied to the host

Control measures applied to the host range from relatively easily administered immunization to behavioural changes that may be extremely difficult for an individual to accept and practise. This section details the types of control measures applied to susceptible hosts and gives examples of their application in the control of selected infectious diseases.

Active immunization

One of the most efficient control measures applied to a host is one that renders the host immune from infectious disease by an infectious agent. Active immunization is a cornerstone of public health measures for the control of many infectious diseases and is considered one of the most cost-effective methods of individual, institutional, and community protection for vaccine-preventable infectious diseases. The most powerful example of the potential impact of active immunization against an infectious disease is that of smallpox vaccination. Mobilization of political will on a worldwide basis, coupled with full application of the strategies of active surveillance and containment immunization against smallpox, ultimately resulted in the complete global eradication of the disease and cessation of transmission of the infectious agent, variola virus.

Active immunization is usually considered synonymous with the term vaccination, and is the process of administration of an antigen that can induce a specific immune response that protects a susceptible host from an infectious disease. Some draw a distinction between the two terms. Narrowly defined, *vaccination* is the process of administration of an antigen and *immunization* is

the development of a specific immune response. Administering an antigen without evoking an immune response is possible, since no vaccine is 100 per cent effective. Conversely, someone can become immunized even if they were not administered an antigen. For example, the live, attenuated oral polio vaccine viruses can be transmitted from the recipient to other close contacts.

Active immunization can be accomplished through different types of antigens, including the following:

- ◆ *Inactivated toxins*: diphtheria toxoid is an example of a formaldehyde-inactivated preparation of diphtheria toxin that protects against clinically manifest disease, although the immunized person may still become infected with toxin-producing strains of *Corynebacterium diphtheria*. Tetanus toxoid and *Clostridium perfringens* toxoid (pig bel vaccine) are other examples of inactivated toxin preparations.
- ◆ *Inactivated complex antigens*: whole-cell pertussis vaccine is an example of a heat or chemically treated preparation of killed whole pertussis bacteria that protects against clinically manifest disease, although the immunized person may still become infected with *Bordetella pertussis*. Inactivated polio vaccine and inactivated influenza vaccine are other examples of inactivated vaccines.
- ◆ *Purified antigens*: acellular pertussis vaccine is an example of a vaccine composed of isolated and purified immunogenic pertussis antigens. Other vaccines with purified components include polyvalent capsular polysaccharide pneumococcal, polysaccharide meningococcal, protein-polysaccharide conjugate *Haemophilus influenzae* type b, and plasma-derived hepatitis B vaccines.
- ◆ *Recombinant antigens*: hepatitis B recombinant vaccine is an example of a vaccine composed of hepatitis B surface antigen subunits made through recombinant DNA technology. Human papillomavirus vaccine is another example of a DNA recombinant vaccine.
- ◆ *Live, attenuated vaccines*: measles vaccine is an example of a vaccine containing live infectious agents that are of reduced virulence, but induce protective antibodies against measles viruses. Other live, attenuated vaccines include oral polio, mumps, rubella, yellow fever, and bacille Calmette–Guérin (BCG) vaccines.

Protective *antibody responses* usually take 7–21 days to develop. Although most vaccines must be given before exposure to be effective, some vaccines may protect even if administered after exposure to an infectious agent. For example, measles vaccine may provide protection against measles disease if given within 72 hours of exposure. This occurs since the percutaneous route of administration of the antigen evokes an immune response faster than the measles virus results in disease through the respiratory route of natural exposure.

Duration of protection varies from only months, such as with killed whole-cell cholera vaccine, to years or even life with some live attenuated vaccines, such as measles vaccine. Some inactivated toxoids and vaccines, such as tetanus toxoid, may require a priming series of doses to be optimally effective and additional booster doses to maintain protective antibodies. Many new technologies are being explored that may increase the number and

efficacy of vaccines available against infectious disease, including immune stimulating complexes, live viral or bacterial vector vaccines, and timed-release vaccines.

It should be recognized that vaccines vary in their efficacy and no vaccine is 100 per cent effective. *Vaccine efficacies* vary with type of vaccine, manufacturing techniques, storage and handling conditions, skill of administration, age of vaccination, and other host factors. Vaccines for routine use are safe. However, no vaccine is 100 per cent safe. Potential vaccinees, or their parents or guardians, should be screened for contraindications and be informed of potential side effects.

Immunization schedules for the routine control of infectious diseases preventable by immunization vary between countries and are usually based on expert advice to governments and physicians. For example, recommended policies for immunization in the United States are provided by the Advisory Committee on Immunization Practices (ACIP) and are published in the *Morbidity and Mortality Weekly Report* (ACIP 2012). In addition, the American Academy of Pediatrics periodically publishes comprehensive immunization recommendations in its *Report of the Committee on Infectious Diseases* (Committee on Infectious Diseases 2012). At the global level, the WHO publishes recommended immunization schedules and control strategies for vaccine-preventable diseases that are periodically updated by expert advisory groups in the *WHO Weekly Epidemiological Record*.

In *outbreak settings*, immunization schedules may be modified. For example, the age of immunization for measles may be lowered to 6 months of age during a measles outbreak. In such situations, people receiving vaccine before the routinely recommended age of immunization should be immunized again at the recommended age since immunization at the earlier age may not have been optimally effective.

Immunization programmes include vaccines for routine child, routine adult, travel, selected high-risk populations, and occupational settings. For example, tetanus toxoid is universally recommended; yellow fever vaccine is only recommended in geographic areas of epidemiological risk (i.e. in certain areas of Africa and South America); typhoid fever vaccine is only recommended for individuals subject to unusual exposure to typhoid, including people living in the same household as known carriers; and anthrax vaccine is only recommended for veterinarians and people occupationally exposed to possibly contaminated industrial raw materials.

Beyond protection of the individual, vaccination may also provide a degree of community protection. This phenomenon is known as herd immunity. *Herd immunity* is the relative protection of a population group achieved by reducing or breaking the chains of transmission of an infectious agent because a sufficient percentage of the population is immune, that is, resistant to infection through immunization or prior natural infection. When the immunity level in a population becomes such that the effective reproduction number of the disease in that population, R , is less than 1, the disease will eventually die out. Herd immunity is a complex phenomenon and varies according to the infectious agent, its routes of transmission, the degree to which immunization protects against infection versus only clinically manifest disease, and the distribution of immunization in the population. Typically, for childhood vaccine-preventable diseases, the immunity levels in the population to achieve herd immunity range from

around 84 per cent (for rubella) to over 90 per cent (for pertussis). The mechanisms of herd immunity are several, including 'direct protection of vaccinees against disease or transmissible infection and indirect protection of non-recipients by virtue of surreptitious vaccination, passive antibody, or just reduced sources of transmission and, hence, risks of infection in the community' (Fine 1993).

A particularly difficult problem for vaccine-preventable infectious disease control programmes is complacency by the population that can result from the very successes of the programmes and highlights the continuing need to educate the public and decision-makers. Low rates of vaccine-preventable infectious disease may mistakenly lead parents to consider that vaccination is no longer important for maintaining their children's health and may result in political leaders reducing funding for immunization programmes. Low disease rates may also focus undue attention on the relatively rare serious side effects of vaccination in relation to current rates of disease. Such side effects should only be compared in relation to rates of disease and its complications that would occur without immunization programmes.

A comprehensive treatment of active immunization is given by Plotkin et al. (2008).

Passive immunization

Passive immunization is a temporary immunity in a host due to the protection afforded by antibody produced in another host. Passive immunity may be acquired either naturally or artificially.

Naturally acquired passive immunity is achieved through transfer of maternal antibodies via the placenta. It is the way that newborn infants are provided with a temporary immunity against many infectious diseases for which the mother is immune. This immunity wanes over time and eventually leaves the infant susceptible to these diseases.

An important use of transplacental immunity as a control measure is in the prevention of tetanus neonatorum (neonatal tetanus) by immunization of women before or during pregnancy with tetanus toxoid. This is especially important in developing countries where the disease typically occurs when the umbilical cord is cut with an unclean instrument contaminated with tetanus spores or when substances contaminated with tetanus spores are placed on the umbilical stump after delivery. Control by active immunization of the infant cannot be achieved in sufficient time since the average incubation period is only 6 days (with a range from 3 to 28 days). An adequately immunized mother, however, will usually effectively transfer maternal antibodies against tetanus across the placenta to her newborn and prevent tetanus neonatorum.

Another example of naturally acquired passive immunity is the relative protection against measles disease in a young infant born to a mother who previously had the disease. Typically, such infants are immune for approximately 6–9 months or more after birth, depending upon how many residual maternal antibodies are present at the time of pregnancy. Other diseases for which there is usually an effective transplacental immunity in infants, for variable amounts of time, include diphtheria, mumps, poliomyelitis, rubella, and varicella (chickenpox). It should be noted that if the mother is not immune, or if residual maternal antibodies have significantly waned, then the infant may be susceptible to disease.

Research is ongoing as to other infectious diseases that may be preventable in the neonate or infant through immunization of the mother before or during pregnancy. Examples include

Haemophilus influenzae type b and group B streptococcal and meningococcal diseases (Insel et al. 1994). Many diseases, however, are not prevented by transplacental immunity.

Breastfeeding is a form of naturally acquired passive antibody transfer to neonates and infants. Breast milk and colostrum contain secretory immunoglobulin A (IgA) antibodies that may play a protective role in the prevention of infections with such agents as respiratory syncytial virus, rotavirus, and *Haemophilus influenzae* type b.

Artificially acquired passive immunity is acquired through administration of an antibody-containing preparation, antiserum, or immune globulin. It has a place in the control of certain infectious diseases in special situations. This immunity also wanes over a relatively short period of time.

Examples of the use of artificially acquired passive immunity to control infectious disease include the following:

- ◆ *Rabies*: natural immunity to rabies in humans does not exist. Susceptible individuals bitten by an animal known or suspected to be rabid should receive rabies immune globulin to neutralize the rabies virus in the wound. It should be noted that, besides passive immunization with rabies immune globulin, such individuals should also receive active immunization with rabies vaccine.
- ◆ *Hepatitis A*: in areas where sanitation is poor, hepatitis A infection commonly occurs at an early age and therefore most adults in developing countries are already immune. However, epidemics may occur in industrialized countries. Passive immunization with immune globulin may be given to: (1) all household and sexual contacts of patients with hepatitis A, (2) other food handlers in an establishment where hepatitis A has occurred in a food handler, (3) all individuals in an institution where a focal outbreak of hepatitis A has occurred, and (4) people from industrialized countries travelling to highly endemic areas. It should be noted that vaccines for active immunization for hepatitis A are now available.
- ◆ *Diphtheria*: treatment of this disease is an example of the use of an antibody containing product (diphtheria antitoxin) produced in an animal (only diphtheria antitoxin from horses is available) administered as part of the treatment regimen for secondary prevention of disease. In suspected cases of diphtheria, the antitoxin must be given as soon as possible because it is only effective in neutralizing diphtheria toxins not yet bound to cells.
- ◆ *Other important infectious diseases, including hepatitis B, measles, tetanus, varicella*: depending upon the circumstances of exposure, susceptibility of the host, and status of the host's general immune system there are circumstances under which hepatitis B immune globulin, tetanus immune globulin, varicella-zoster immune globulin, or immune globulin may be warranted.

Chemoprophylaxis

Chemoprophylaxis is the prevention of infection or its progression to clinically manifest disease through the administration of chemical substances, including antibiotics. Chemoprophylaxis can also consist of the treatment of a disease to prevent complications of that disease. Chemoprophylaxis may be

specifically directed against a particular infectious agent or it may be non-specifically directed against many infectious agents. The use of antibiotics before surgical procedures is an example of non-specific chemoprophylaxis to prevent wound infections in the postoperative period. Examples of specific chemoprophylaxis are given below.

The use of chemoprophylaxis to *prevent development of infection* is illustrated by using chloroquine to prevent malarial parasitaemia caused by *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and chloroquine-sensitive strains of *Plasmodium falciparum*. For some chloroquine-resistant strains of *Plasmodium falciparum*, alternative regimens include mefloquine alone, doxycycline alone, primaquine alone, or an atovaquone/proguanil combination. Primaquine may be given to reduce the risk of a relapse from intrahepatic forms of *Plasmodium vivax* and *Plasmodium ovale* after discontinuation of chemoprophylaxis with any chemosuppressive drugs other than primaquine. Determination of a specific malaria chemoprophylactic regimen is complex. It must take into account the geographic area, the possibility of pregnancy, the weight of an individual (dose size for children is determined by body weight), and the risks of adverse reactions to the chemoprophylactic regimen.

Other examples of prevention of development of infection include the following:

- ◆ The use of silver nitrate, erythromycin, or tetracycline instilled into the eyes of a newborn to prevent gonococcal ophthalmia by transmission of *Neisseria gonorrhoeae* from an infected mother during birth.
- ◆ The use of tetracycline, sulphonamides (including sulfadiazine and trimethoprim-sulfamethoxazole), chloramphenicol, or streptomycin in close contacts of confirmed or suspected cases of plague pneumonia to prevent plague pneumonia by transmission of *Yersinia pestis*.
- ◆ The use of benzathine penicillin in those in sexual contact with confirmed cases of early syphilis to prevent syphilis by transmission of *Treponema pallidum*.

An example of the use of chemoprophylaxis to *prevent the progression of an infection to active manifest disease* is the use of isoniazid (INH) to prevent the progression of latent infection with *Mycobacterium tuberculosis* to clinical tuberculosis. People less than 35 years of age who are tuberculosis test positive should receive INH to prevent clinical tuberculosis. The decision to use INH, especially in individuals more than 35 years of age (who are at higher risk of clinical hepatitis from the use of the drug), must be determined based on such information as length of infection, closeness of association with a current case, status of the immune system, presence of acute liver disease, possibilities of pregnancy, and risks of adverse reactions.

Other examples of prevention of progression of an infection to active manifest disease through the use of chemoprophylaxis include the following:

- ◆ Co-trimoxazole or pentamidine to prevent subclinical latent infection with *Pneumocystis jirovecii* (formerly *carinii*) from progressing to clinically manifest *Pneumocystis* pneumonia in immunosuppressed people such as HIV-infected individuals.

- ◆ Mebendazole, albendazole, or pyrantel pamoate to prevent infection with *Necator americanus*, *Ancylostoma duodenale*, and *Ancylostoma ceylanicum* from progressing to the clinically manifest anaemia of hookworm disease.
- ◆ Pyrimethamine combined with sulfadiazine and folinic acid (to avoid possible bone marrow depression) to prevent asymptomatic infants congenitally infected with *Toxoplasma gondii* from progressing to clinically manifest chorioretinitis and other sequelae of congenital toxoplasmosis.

In some situations, establishing screening programmes to detect and treat asymptomatic infections or unrecognized disease in defined populations is useful. An example is the screening for *Chlamydia trachomatis* in sexual partners of people infected with *Chlamydia trachomatis*, women with mucopurulent cervicitis, sexually active women 25 years of age or younger, and women older than 25 years of age with risk factors for chlamydia. A more detailed background on screening as a public health function is given in Chapter 11.4.

An example of the use of chemoprophylaxis to *treat an infectious disease to prevent complications of the disease* is the use of penicillin (or erythromycin in penicillin-sensitive patients) to treat streptococcal sore throats caused by *Streptococcus pyogenes* group A to prevent acute rheumatic fever.

Other examples of prevention of complications of an infectious disease through the use of chemoprophylaxis include the following:

- ◆ Tetracycline for adults, or penicillin for children, for treatment of Lyme disease caused by *Borrelia burgdorferi* in the erythema chronicum migrans stage to prevent or reduce the severity of late cardiac, arthritic, or neurological complications.
- ◆ Benzathine penicillin for treatment of syphilis in its primary, secondary, or early latency period to prevent late manifestations of the disease such as cardiovascular syphilis.
- ◆ Ketoconazole for treatment of blastomycosis caused by *Blastomyces dermatitidis* in its early stages to prevent progression of chronic pulmonary or disseminated blastomycosis that may lead to death.

Potential problems with the use of chemoprophylaxis may include compromise of the host's own non-specific defence mechanisms, other replacement infectious agents causing disease by growing in the place of the infectious agent affected by the specific chemoprophylactic regimen (e.g. severe diarrhoea from intestinal infections with *Clostridium difficile* may occur when the normal bacteria flora in the intestines have been lost due to antibiotics), and emergence of resistant strains of the infectious agent. The development of antibiotic resistance can be reduced by using antibiotics only when needed, selecting the proper antibiotic (or, in some situations, the appropriate multidrug therapy) for the infectious agent, and ensuring compliance with the appropriate regimen for the duration of treatment.

Behavioural change

Perhaps the most challenging tool for the control of infectious diseases, and sometimes one of the most powerful and cost-effective, is behaviour change in the host that reduces or eliminates risk of exposure to an agent. Everyone has developed habits of living

(lifestyles) that are not easily changed. Some of these behaviours are protective against infectious diseases. Others render the individual at higher risk of infection.

Examples of higher risk of exposure to infectious agents through behaviour, and behaviour changes that can have an impact on the chain of transmission, include the following.

Sexual behaviour

Many infectious agents are transmitted by the direct transmission route through sexual contact, including *Chlamydia trachomatis* causing chlamydial genital infections, *Neisseria gonorrhoeae* causing gonorrhoea, *Treponema pallidum* causing venereal syphilis, *Calymmatobacterium granulomatis* causing granuloma inguinale, *Haemophilus ducreyi* causing chancroid, herpes simplex virus causing herpes simplex, *Trichomonas vaginalis* causing trichomoniasis, human papillomaviruses causing condyloma acuminata, and HIV causing AIDS.

Abstinence behaviour, that is, refraining from sexual activity with other people, eliminates the risk of transmission of these agents through sexual contact. The delaying of age of first sexual activity avoids the risk of transmission of these agents at an early age. Restricting sexual contact to only between two uninfected people who do not have sexual activity with any other people virtually eliminates the risk of transmission of these agents through sexual behaviours. The exceptions are due to other routes of transmission of some of these agents (e.g. HIV acquired through intravenous drug use in one partner being transmitted through sexual contact to the other partner). Limiting the number of sexual partners, and limiting those sexual partners to people who also have few sexual partners, reduces the risk of exposure. However, at the individual level, if one of these sexual partners has an infectious agent transmissible by sexual contact, the risk of transmission may still be high. Finally, condom use during sexual activity in high-risk situations will markedly reduce, but not eliminate, transmission. A more detailed background on sexually transmitted diseases is provided in Chapter 8.12.

Intravenous drug use behaviour

Injection of drugs using non-sterile needles or syringes previously used by other intravenous drug users may transmit infectious agents in blood through the vehicle-borne route of indirect transmission, including HIV causing AIDS; hepatitis B virus causing viral hepatitis B; and *Plasmodium vivax*, *Plasmodium malariae*, and *Plasmodium ovale* causing malaria.

Abstinence behaviour, that is, refraining from intravenous drug use, eliminates the risk of transmission of such agents through contaminated needles and syringes. Using a sterile needle and sterile syringe for intravenous drug use will break the chain of transmission of these infectious agents through this route. Some community public health programmes, in addition to promoting drug abstinence and drug rehabilitation, conduct needle and syringe exchanges and education regarding methods of decontamination to help promote the use of sterile injection equipment among intravenous drug users (see Chapter 9.2).

Eating behaviour

Eating certain foods may result in exposure to infectious agents through the vehicle-borne route of indirect transmission. These behaviours include consuming raw molluscs by which an infectious agent like the hepatitis A virus can cause viral hepatitis A,

eating raw eggs by which an infectious agent like a *Salmonella* serotype can cause salmonellosis, and consuming raw beef by which an infectious agent like *Taenia saginata* can cause beef tapeworm infection.

Although food and diet are strongly ingrained behaviours, modification of dietary patterns is possible. Cooking foods like beef, pork, and eggs can markedly reduce risk of transmission of infectious agents. In addition, reducing risks by elimination of infectious agents from the food may be possible (see the section on control methods applied to the environment). Eating shortly after cooking so that foods are not left standing at ambient temperatures for extended times and paying attention to food recalls are also important behaviours. Hand washing before eating also reduces risk of transmission of many infectious agents that are spread through direct or indirect routes of faecal–oral transmission, such as *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei* which may cause shigellosis (bacillary dysentery), which is estimated to cause 600,000 deaths per year with two-thirds of the cases in children under 10 years of age (Heymann 2010).

Working behaviour

In certain occupations, many behaviours may result in exposure to infectious agents and should be targets for control programmes in occupational safety and health settings. Specific examples include the following:

- ◆ Dental workers performing procedures with bare hands may result in exposure to hepatitis B viruses from infected patients.
- ◆ Health workers improperly handling used needles may result in needle-stick injuries leading to exposure to HIV from infected patients.
- ◆ Hospital laboratory workers improperly processing specimens containing infectious agents without appropriate glove or eye-wear protection may result in exposure to these agents.
- ◆ Veterinarians who do not properly handle animals may result in brucellosis (undulant fever) due to exposure to *Brucella abortus*, *Brucella melitensis*, *Brucella suis*, or *Brucella canis*.

Occupational hazards related to non-infectious materials may predispose an individual to increased risk of infectious diseases. For example, working conditions and behaviours in industrial plants and mines that lead to silicosis due to long-term inhalation of free crystalline silica dust will greatly increase the risk of developing tuberculosis.

Working behaviours appropriate for the particular occupational setting may include wearing protective clothing, eyewear, and gloves; hand washing and changing clothes after work; receiving appropriate vaccinations for the working environment; meticulous adherence to needle disposal and equipment sterilization procedures; and using hooded laboratory benches when handling infectious specimens that can become aerosolized.

Other behaviours

Other behaviours that may reduce the transmission of infectious agents include the following:

- ◆ Scheduling outdoor activities at periods of low vector activity, applying insect repellents and sleeping under bednets reduce

the indirect transmission of vector-borne agents of infectious diseases like malaria.

- ◆ Searching oneself for attached ticks every 3 to 4 hours when playing or working in tick-infested areas reduces the indirect transmission of vector-borne agents of infectious diseases like Rocky Mountain spotted fever.
- ◆ Avoiding sharing of utensils, cups, toothbrushes, or towels reduces the indirect transmission of vehicle-borne agents of infectious diseases like mononucleosis.
- ◆ Wearing of shoes reduces the direct transmission of infectious agents like those causing hookworm disease.
- ◆ Frequently bathing and regular washing of clothes in hot soapy water controls body lice.
- ◆ Breastfeeding reduces diarrhoeal diseases in the infant, although it may transmit HIV from HIV-infected mothers.
- ◆ Hand washing after defecation or touching potentially contaminated surfaces, people, or animals (including those found in petting zoos) prior to preparing food or touching one's own eyes, mucous membranes, or mouth reduces the risk of direct or indirect transmission of a wide variety of infectious agents.
- ◆ Large family sizes and crowding may facilitate airborne transmission of infectious agents in droplet nuclei for infectious diseases like tuberculosis.

Some of these other behaviours, like crowding, are conditioned by circumstances such as poverty that are not easily or directly amenable to programmes promoting behavioural change.

Reverse isolation

Certain rare circumstances exist where a means of avoiding transmission of an infectious disease to a highly susceptible host is to provide reverse, or protective, isolation. Such isolation attempts to protect infection-prone patients from potentially harmful infectious agents. Reverse isolation procedures range from provision of a private room with the use of masks, gloves and gowns by all people entering the room, to elaborate facilities with laminar airflow rooms and sterilization of all food. Protective isolation is usually conducted for a limited time until the normal immune system recovers, a regimen of passive immunization is begun, or a bone marrow transplant is successful.

Examples of people who may need periods of reverse isolation include those who have such diseases as X-linked agammaglobulinemia, DiGeorge's syndrome, and severe combined immunodeficiency; or those who have received therapies, such as some forms of cancer chemotherapy, that have severely compromised the person's immune system in combating many infectious diseases.

Barriers

One tool of control that can be applied to the host is the use of barriers between the host and the infectious agent. The effectiveness of such barriers, however, may be dependent on the behaviour of the host to use them consistently and education to use them correctly. Examples of barriers include the following:

- ◆ Screens, bednets (including bednets impregnated with pyrethroid insecticides such as permethrin), long-sleeved shirts and trousers (with the cuffs tucked into boots as a mechanical

barrier), and repellents (such as N,N-diethyl-meta-toluamide known as DEET) to prevent transmission of malaria through the bite of infected female *Anopheles* mosquitoes or West Nile virus through *Culix* mosquitoes.

- ◆ Condoms to prevent transmission of HIV and other sexually transmitted infectious agents through sexual intercourse.
- ◆ Masks (air-purifying respirators) to prevent transmission of tuberculosis through airborne droplet nuclei from patients with sputum-positive pulmonary tuberculosis.

General improvement in host resistance

Improving host resistance through general improvement of the immune system is a non-specific approach, but may be important in certain settings. Kwashiorkor, marasmus, and other forms of malnutrition debilitate the host's immune system and may make an individual more susceptible to infectious diseases. Moreover, people who are malnourished and succumb to an infectious disease are at higher risk of the disease being of greater severity and leading to other complications.

Malnutrition also encompasses micronutrient deficiencies. Vitamin A deficiency, for example, has been linked to higher rates of mortality associated with measles disease. Correcting vitamin A deficiency, through programmes of supplementation, fortification and dietary modification in high-risk populations, can reduce mortality rates due to measles.

A complex interaction exists between infectious diseases, such as diarrhoeal diseases, and malnutrition. A downward spiral of infection may lead to malnutrition that, in turn, leads to more infections, and so on. If unchecked, especially in developing countries, this downward spiral can ultimately result in death.

International travel

The special situation of international travel combines many control measures applied to the host already mentioned. The increase in the numbers of travellers, the speed of travel, and the ability to reach areas previously infrequently visited have reduced the effectiveness of surveillance for infectious diseases at ports of arrival and increased infectious disease risks. Advice for prevention against infectious diseases must be both general and specific.

General advice includes such issues as avoidance of eating and drinking potentially contaminated food or drink (including ice) and swimming or bathing in polluted water. Specific advice provided by health professionals should be provided based on information about the area to be visited and may include such measures as active immunization against yellow fever, active or passive immunization against hepatitis A, chemoprophylaxis against malaria, repellents against potentially infected mosquitoes, and not walking barefoot in areas of risk for infection with hookworms *Strongyloides stercoralis* and *Strongyloides fuelleborni*. A more detailed background on international travel and health is provided in the annually updated WHO publication on *International Travel and Health* (WHO 2012b).

Control measures applied to vectors

Vector-borne transmission is the only or main route of transmission for many infectious diseases. There exist more than 100 arthropod-borne viruses that may produce clinically manifest

diseases in humans. Control of vector-borne diseases includes measures to: (1) change behaviour and create barriers to the susceptible host, (2) reduce or break the chain of transmission of the infectious agent from an infected host to the vector, and (3) directly control the vector population itself. Chemical, environmental, and biological controls are the primary means of directly controlling the vector population.

Chemical control

Chemicals used in the control of vectors that act as digestive poisons, contact poisons, or fumigants include minerals, natural plant products (botanicals), chlorinated hydrocarbons, organophosphates, carbamates, and fumigants. Chemical control measures include the following public health interventions:

- ◆ Spraying chemical insecticides such as organochlorine insecticides (e.g. dichlorodiphenyltrichloroethane, or DDT, and dieldrin), organophosphorus insecticides (e.g. malathion and fenitrothion), and carbonate insecticides (e.g. propoxur and carbaryl) to prevent malaria through control of mosquitoes.
- ◆ Spraying chemical biodegradable insecticides such as temephos (Abate®) to prevent onchocerciasis through control of *Simulium* fly vectors.
- ◆ Using traps impregnated with decamethrin to prevent African trypanosomiasis (sleeping sickness) through reduction of the population of infective species of *Glossina* (tsetse fly) vectors.
- ◆ Treating snail breeding places with chemical molluscicides to prevent schistosomiasis due to the free-swimming cercariae (larval forms) of *Schistosoma mansoni*, *Schistosoma haematobium*, and *Schistosoma japonicum* that develop in snails.
- ◆ Treating step-wells and ponds with chemical insecticides such as temephos (Abate®) to prevent dracunculiasis due to infected cyclops (a crustacean copepod).
- ◆ Suppressing rat populations by poisoning, preceded or accompanied by measures to control fleas, as an additional measure to supplement environmental sanitation to control rodent populations to prevent human plague.

The use of spraying for control of mosquitoes is complicated due to concerns about environmental contamination by chemicals such as DDT and dieldrin which have led to them being banned in many countries. In addition, the emergence of mosquito vectors resistant to the insecticides diminishes their effectiveness in many areas. New methods of application, such as ultra-low-volume spraying of malathion, reduce the amounts of insecticide used.

Environmental control

Environmental control of vectors includes the following public health interventions:

- ◆ Eliminating breeding sites of mosquito larvae by filling and draining areas of stagnant water and removing objects around houses that may collect water.
- ◆ Destroying the habitats of the tsetse fly vector.
- ◆ Properly implementing landfill procedures, placing lids on rubbish bins, covering food for human consumption, screening privies, cleaning up spilled food, and appropriately storing food.

- ◆ Placing roach and fly traps.
- ◆ Constructing rat-proof houses.
- ◆ Eliminating rodent habitats.

It is also important to note that certain development projects may have an impact on the environment that facilitates the growth of vector or intermediate-host populations and results in increased infectious diseases. Construction of artificial waterways may serve as breeding sites for *Simulium* fly vectors that can transmit *Onchocerca volvulus* resulting in onchocerciasis. Irrigation schemes can foster the growth of snail intermediate hosts required for the transmission of species of *Schistosoma* resulting in schistosomiasis. Carefully conducted environmental and health impact studies that consider the impact of a construction project on the vector and intermediate host populations, and ways to modify the project to reduce such populations, are important environmental control measures.

Biological control

Biological control of vectors includes the following public health interventions:

- ◆ *Introduction of predators and parasites*: the introductions of *Gambusia affinis*, a small fish that feeds on mosquito larvae, and of *Coelomomyces*, a fungal parasite, are examples of control measures that are effective against *Aedes* mosquitoes.
- ◆ *Insect growth regulators*: the use of such regulators may result in death or sterility of vectors by interfering with normal insect development. An example is the use of methoprene (Altosid®) to control flood water mosquitoes.
- ◆ *Genetic modification*: although still at an experimental phase, researchers have developed transgenic, or genetically modified, mosquitoes that are malaria resistant with higher survival rates that could eventually replace mosquitoes that carry malaria parasites.

Control measures applied to infected humans

Control measures may be applied to infected people at the individual level, in the institutional or hospital setting, and at the community level.

Hospital infection control

The hospital setting is a unique situation that requires special efforts to prevent and control nosocomial infections, or healthcare-associated infections (HAIs), which are infections that originate or occur in a hospital or other healthcare setting. HAIs are a major problem worldwide. In the United States alone, some 2 million HAIs occur annually resulting in an estimated 90,000 deaths (McKibben et al. 2005). It has been estimated that HAIs result in some US\$35.7–45 billion in annual direct medical hospital patient costs based on using the Consumer Price Index for inpatient hospital services (Scott 2009).

Infection control programmes for hospitals should ideally include the following elements:

- ◆ An infection control committee responsible for overall coordination of infection control activities.

- ◆ One or more infection control practitioners responsible for nosocomial disease surveillance, analysis of data, consultation, and training of hospital staff.
- ◆ A hospital epidemiologist to supervise the infection control practitioners, oversee data collection and analysis, and implement any needed emergency infection control measures.
- ◆ An engineer to direct engineering and preventive maintenance operations, especially ventilation equipment.
- ◆ A sanitarian to develop procedures for proper disposal of liquid and solid wastes; and sanitation of water, ice, and food.
- ◆ Effective guidelines for patient care practices.
- ◆ Surveillance of patient care practices, patient infections, and environmental contamination by infectious agents.
- ◆ Coordination with other departments (microbiology laboratory, central services, housekeeping, food service, and laundry).
- ◆ Vector control.
- ◆ Thorough investigation of problems.

Examples of specific control measures that may be applied to infected humans at the individual, institutional and community levels are detailed as follows.

Chemotherapy

Treatment of people with infectious diseases or subclinical infections may be a control tool for some infectious diseases. Such treatment may or may not have an impact on disease progression in the patient. It should be noted that rapid case detection and prompt application of appropriate chemotherapeutic agents are needed to limit infectivity.

Some important examples of control by chemotherapy include the following:

- ◆ Treatment of patients with sputum-positive pulmonary *tuberculosis* with appropriate multidrug therapy will usually result in sputum conversion rendering them non-infectious to others within a few weeks. Recommended treatment regimens include isoniazid (INH) combined with one or more of the following antibiotics: rifampin, streptomycin, ethambutol, and pyrazinamide. The WHO has recommended that adherence to a complete course of multidrug therapy be directly observed by another responsible person as part of the DOTS (directly observed treatment, short-course) global strategy for the control of tuberculosis.
- ◆ Patients with *leprosy* treated with appropriate multidrug therapy are considered no longer infectious within 3 months of regular and continued treatment. Recommended treatment regimens for multibacillary leprosy include the following antibiotics: rifampin, dapsone, and clofazimine.
- ◆ Treatment of patients with *streptococcal sore throats* with penicillin (or erythromycin for penicillin-sensitive patients) will usually render them no longer infectious after 24–48 hours.
- ◆ Patients with *pertussis* treated with antibiotics such as erythromycin or trimethoprim-sulfamethoxazole, although they may not affect the patient's symptoms, will usually result in the patient no longer being infectious after 5–7 days.

Of special note is the situation of treatment of people who are carriers:

A person or animal that harbors a specific infectious agent without discernible clinical disease, and which serves as a potential source of infection. The carrier state may exist in an individual with an infection that is unapparent throughout its course (such an individual is commonly known as *healthy or asymptomatic carrier*), or during the incubation period, convalescence, and post-convalescence of a person with a clinically recognizable disease (commonly known as *incubatory or convalescent carrier*). Under either circumstance the carrier state may be of short or long duration (*temporary or transient carrier, or chronic carrier*). (Heymann 2010)

A chronic carrier of diphtheria, for example, may shed the infectious agent *Corynebacterium diphtheriae* for 6 months or more, but appropriate antibiotic therapy will usually promptly stop the carrier state. Another example is that of untreated patients with typhoid fever due to *Salmonella typhi*. Between 2 to 5 per cent of such patients will become permanent carriers. Treatment with appropriate antibiotics may be effective in ending the carrier state.

Antibiotic treatment may not always eliminate a carrier state for some infectious agents. For example, the treatment of people with salmonellosis with an antibiotic may not terminate the period of communicability and can even result in emergence of antibiotic-resistant strains. However, antibiotic therapy may be still warranted under certain circumstances.

In some situations, establishing screening programmes in defined target populations for identification of asymptomatic or unrecognized infections that could be transmitted to others may be appropriate. Such screening should include the necessary follow-up with appropriate chemotherapy and counselling. An example would be screening close contacts of diphtheria patients with nose and throat cultures for the presence of *Corynebacterium diphtheriae*. Identified carriers with positive cultures should be treated with appropriate antibiotic therapy.

Isolation

Isolation is the 'separation, for a period at least equal to the *period of communicability*, of infected persons or animals from others, in such places and under such conditions as to prevent or limit the direct or indirect transmission of the infectious agent from those infected to those who are susceptible to infection or who may spread the agent to others' (Heymann 2010).

The US CDC and the Hospital Infection Control Practices Advisory Committee (HICPAC) have provided guidelines for isolation precautions in hospital settings (Siegel et al. 2007). There are two levels of isolation precautions, namely: (1) a standard precautions level designed for the care of all hospitalized patients, and (2) a transmission-based precautions level designed for the care of hospitalized patients that are suspected or confirmed to be infected by agents spread by contact, droplet, or airborne routes of transmission. These are summarized from guidelines as follows.

Standard precautions are universally applied precautions designed to reduce the risk of transmission by infectious agents from blood; body fluids, secretions, and excretions; non-intact skin; and mucous membranes. The essential elements of standard precautions include handwashing; personal protective equipment (use of gloves, appropriate application of mask and eye protection or a face shield, and utilization of gowns); proper handling of patient-care equipment; adequate environmental control

measures for routine care, cleaning, and disinfection of frequently touched surfaces; appropriate handling, transporting, and processing of used linen; proper handling and disposal of needles, scalpels, and other sharp instruments; adequate protection when undertaking patient resuscitation; respiratory hygiene/cough etiquette; and placement of patients who contaminate the environment in private rooms.

Airborne precautions are used, in addition to standard precautions, in settings where patients are suspected or confirmed to be infected by agents transmitted by airborne droplet nuclei. The essential elements of airborne precautions include preferably placing patients in an airborne infection isolation room (AIIR) that has monitored negative air pressure (if necessary, it is possible to use cohorting of patients with the same active infections); use of mask respirators (N-95 air-purifying respirators); and limiting patient movement and transport from the room (placing a surgical mask on the patient if they are being moved for an essential purpose). An example of an infectious disease for which patients are recommended to be placed under airborne precautions is a patient in hospital with measles through the fourth day of rash. Although isolation of patients with measles not in hospital is not practical in the general population, schoolchildren should remain out of school until at least the fourth day of rash.

Droplet precautions are used, in addition to standard precautions, in settings where patients are suspected or confirmed to be infected by agents transmitted by droplets. The essential elements of droplet precautions include placement of patients in a private room (if necessary, it is possible to use cohorting of patients with the same active infections or maintaining a spatial separation of at least 3 feet between the infected patient and other patients and visitors); use of a mask when working within 3 feet of the patient; and limiting patient movement and transport from the room (placing a surgical mask on the patient if they are being moved for an essential purpose). Examples of infectious diseases for which patients are recommended to be placed under droplet precautions include pharyngeal diphtheria caused by *Corynebacterium diphtheriae* and pneumonic plague caused by *Yersinia pestis*.

Contact precautions are used, in addition to standard precautions, in settings where patients are suspected or confirmed to be infected or colonized by agents transmitted by direct or indirect contact. The essential elements of contact precautions include placement of the patient in a private room (if necessary, it is possible to use cohorting of patients with the same active infections); use of gloves when entering the patient's room and removing them before leaving the room; wearing a gown when entering the patient's room and removing the gown before leaving the room; limiting patient movement and transport to essential purposes only; and, when possible, dedicate the use of patient-care equipment to a single patient (if necessary, it is possible to use such equipment on a cohort of patients with the same active or colonized infections). Examples of infectious diseases for which patients are recommended to be placed under contact isolation precautions include cutaneous diphtheria caused by *Corynebacterium diphtheriae*, rubella, and disseminated herpes simplex caused by herpes simplex virus.

Quarantine of potentially infected persons

Quarantine is the 'Restriction of activities for well persons or animals who have been exposed (or are considered to be at high risk

of exposure) to a case of communicable disease during its period of communicability (i.e., *contacts*) to prevent disease transmission during the incubation period if infection should occur' (Heymann 2010).

Two categories of quarantine are as follows (Heymann 2010):

Absolute or complete quarantine: the limitation of freedom of movement of those exposed to a communicable disease for a period of time not longer than the longest usual incubation period of that disease, in such a manner as to prevent effective contact with those not so exposed.

Modified quarantine: a selective, partial limitation of freedom of movement of contacts, commonly on the basis of known or presumed differences in susceptibility and related to the assessed risk of disease transmission. It may be designed to accommodate particular situations. Examples are exclusion of children from school, exemption of immune persons from provisions applicable to susceptible persons, or restriction of military populations to the post or to quarters. Modified quarantine includes: *personal surveillance*, the practice of close medical or other supervision of contacts to permit prompt recognition of infection or illness but without restricting their movements; and *segregation*, the separation of some part of a group of persons or domestic animals from the others for special consideration, control or observation; removal of susceptible children to homes of immune persons; or establishment of a sanitary boundary to protect uninfected from infected portions of a population. (Heymann 2010)

Examples of diseases where quarantine may be considered include the following.

- ◆ *Pneumonic plague*: people who have been in the same household or in face-to-face contact with patients with pneumonic plague and who do not accept chemoprophylaxis should be placed under *absolute quarantine* with strict isolation, including careful surveillance, for 7 days.
- ◆ *Measles*: although absolute quarantine is impractical, a *modified quarantine* is recommended in settings where young children are living in dormitories, wards, or institutions. When measles occurs in such institutional settings, strict *segregation* of infants is recommended.
- ◆ *Lassa fever*: close *personal surveillance* of all close contacts is recommended. Such people include those who live or are in close contact with Lassa fever patients as well as laboratory personnel testing specimens from such patients.

Restriction of activities

Controlling infectious disease transmission by restriction of the activities of people in the community who are potentially infectious to others may be appropriate in certain circumstances. Examples include the following:

- ◆ Individuals with a diarrhoeal disease should be excluded from handling food and caring for patients in hospital, children, and elderly people.
- ◆ Known carriers of *Salmonella typhi* should be excluded from food handling and care of patients.
- ◆ People with staphylococcal disease should avoid contact with debilitated people and infants.
- ◆ People with rubella should be excluded from school or work for 7 days after the onset of rash and from contact with pregnant women.

Behavioural change

Behaviour change in an infected person to protect others may be difficult to accomplish and often requires continuing education and counselling. However, this should be considered in preventing the transmission of infectious agents in the following situations.

Sexual behaviour

Examples of infectious agents transmitted through sexual activities are discussed in the earlier section on control measures applied to the host and in more detail in Chapter 8.12. Individuals who suspect that they may have a sexually transmitted disease should be encouraged to have health-seeking behaviours. People with a sexually transmissible infectious agent should be treated and asked to cooperate with health officials to trace their sexual contacts. Patients with diseases such as lymphogranuloma venereum and syphilis, for example, should refrain from sexual contact until all lesions are healed. HIV-infected individuals should be counselled to treat genital ulcer disease promptly since such disease may increase transmissibility of HIV. Also, HIV-infected people should avoid sexual intercourse with HIV-negative individuals or, if having sexual intercourse with HIV-negative individuals, use methods such as condoms to reduce the risk of transmission. For a more detailed overview of HIV and AIDS see Chapter 8.13.

Intravenous drug use behaviour

In addition to counselling to abstain from intravenous drug use and establishing drug rehabilitation programmes to help individuals who wish to abstain, promoting behaviour change in the use of injection equipment is important. Discouraging the sharing of injection equipment and education on methods for the decontamination of needles and syringes for intravenous drug use reduce risks of transmission of infectious agents through contaminated injection equipment.

Food preparation behaviour

Individuals who should be restricted from handling food (e.g. carriers of *Salmonella typhi*) should be counselled regarding their condition and potential to infect others if they handle food. Food handlers who have an infectious disease that is potentially transmissible through the vehicle-borne means of food should be discouraged from handling food for others. The importance of hand washing, especially after defecation and before handling food, should be stressed.

Other behaviours

Other behaviours that may reduce risk of transmission of infectious agents to other people include the following:

- ◆ *Cough and sneeze behaviour*: patients with infectious diseases directly transmitted by droplet spread or airborne transmitted by droplet nuclei (e.g. patients with sputum-positive tuberculosis) should cover their mouth and nose when coughing or sneezing.
- ◆ *Avoidance of contaminated drinking water*: people suffering from dracunculiasis should avoid entering a source of drinking water if they have an active ulcer or blister.
- ◆ *Avoidance of vector bites*: patients with the vector-borne disease of African trypanosomiasis (sleeping sickness) with trypanosomes in their blood should prevent tsetse flies from biting.

- ♦ *Avoidance of donating organs or bodily fluid by certain people:* individuals who are infected with HIV or who have sexual and other behaviours that have placed them at increased risk for HIV infection should not donate blood, plasma, tissues, cells, semen for artificial insemination, or organs for transplantation.

Control measures applied to animals

A zoonosis is any infectious agent or infectious disease that may be transmitted under natural conditions from vertebrate animals, both wild and domestic, to humans. A detailed approach to zoonoses is given in the comprehensive work *CRC Handbook Series in Zoonoses* (Beran and Steele 1994). In the control of zoonoses many approaches are used that are applied to animals, including the following.

Active immunization

Active immunization, or vaccination, of selected animals may protect susceptible animal hosts from certain infectious diseases. This protection of animals, in turn, prevents susceptible humans from exposure to the infectious agent of those diseases from animals. An example of an infectious disease in animals in which some control can be achieved through immunization in selected animal populations is rabies. The reservoir of the rabies virus is varied and includes dogs, foxes, wolves, skunks, raccoons, and bats. Preventive measures include efforts to vaccinate all dogs.

Other examples of immunization of animals under certain conditions include: (1) immunization of young goats and sheep using a live attenuated strain of *Brucella melitensis* and calves using a strain of *Brucella abortus* in areas of high endemicity for brucellosis; and (2) immunization of animals at risk for acquiring infection with *Bacillus anthracis* that could be transmitted to man causing anthrax.

Restriction or reduction

Restriction is the limiting of the movement of animals and includes isolation and quarantine. Reduction is the killing, known as culling, of selected animals. Selective use of restriction of animals or reduction of animal populations that are infected, or potentially infected, with a zoonotic infectious agent are methods used to decrease or eliminate the opportunity of exposure of susceptible humans, or other animals, to such animals.

The example of rabies can also be used to illustrate the use of restriction or reduction of an animal population to help control an infectious disease. Heymann (2010) recommends the following measures:

Preventive measures

1. Register, license, and vaccinate all owned dogs, and other pets when feasible, in enzootic countries; control ownerless animals and strays. Educate pet owners and the public on the importance of local community responsibilities (e.g. pets should be leashed in congested areas when not confined on the owner's premises; strange-acting or sick animals of any species,—domestic or wild—should be avoided and not handled; animals that have bitten a person or another animal should be reported to relevant authorities, such as the police/local health departments; if possible, such animals should be confined and observed as a preventive measure; and wildlife should be appreciated in nature and not be kept as pets). Where animal

population reduction is impractical, animal contraception and repetitive vaccination campaigns may prove effective.

2. Detain and observe for 10 days any healthy-appearing dog or cat known to have bitten a person (stray or ownerless dogs and cats may be euthanized and examined for rabies by fluorescent microscopy); dogs and cats showing suspicious clinical signs of rabies should be euthanized and tested for rabies.

3. Euthanize unvaccinated domestic animals bitten by known rabid animals; if detention is elected, hold the animal in a secure facility for at least 6 months under veterinary supervision, and vaccinate against rabies 30 days before release. If previously vaccinated, booster immediately with rabies vaccine, and detain for at least 45 days.

4. Cooperate with wildlife conservation authorities in programs to reduce the carrying capacity of wildlife hosts of sylvatic rabies, and to reduce exposures to domestic animals and human populations—such as in circumscribed enzootic areas near campsites, and in areas of dense human habitation. (Heymann 2010)

Epidemic (epizootic) measures

In urban areas of industrialized countries, strict enforcement of regulations requiring collection, detention and euthanasia of ownerless and stray dogs, and of non-immunized dogs found off owners' premises; control of the dog population by castration, spaying or drugs have been effective in breaking transmission cycles. (Heymann 2000)

Other measures

Other examples of restricting or reducing of animal populations include the following:

- ♦ Rat-proofing dwellings and reduction of the rat population to prevent rat bites that may transmit the infectious agents *Streptobacillus moniliformis* and *Spirillum minus* causing the rat-bite fevers of streptobacillosis and spirillosis, respectively.
- ♦ Rat suppression by poisoning (after achieving flea control) in rodent populations with a high potential for epizootic plague.
- ♦ Elimination of animals infected with *Brucella abortus*, *Brucella melitensis*, *Brucella suis*, and *Brucella canis* by segregation or slaughter to prevent brucellosis.
- ♦ Slaughtering dairy cattle that test positive for infection with *Mycobacterium bovis*, the infectious agent of bovine tuberculosis.

Chemoprophylaxis and chemotherapy

Chemoprophylaxis of an animal is using chemical substances (e.g. antibiotics) that prevent infection or its progression to clinically manifest infectious disease in the animal. Chemotherapy of an animal is using these chemical substances to treat an infectious disease in an animal. Both chemoprophylaxis and chemotherapy are control measures that may be used to reduce or prevent the opportunity of an infectious agent from being transmitted from an animal to susceptible humans. However, caution should be applied in the routine use of chemoprophylaxis in cattle, feed lots, and poultry farms that can promote the emerging of drug resistance and its associated problems in humans as well.

Psittacosis is an example of a zoonosis controlled by chemoprophylaxis or chemotherapy in selected animal populations. The infectious agent, *Chlamydia psittaci*, may be directly transmitted to humans from infected birds when the dried droppings,

secretions, or dust from the feathers of such infected birds are inhaled. Imported psittacine species of birds should be placed under quarantine and receive an appropriate antibiotic chemotherapeutic regimen such as chlortetracycline administered in their feed for 30 days.

Another example is chemoprophylaxis in selected dogs at high risk of infection with *Echinococcus granulosus*. This infectious agent can be transmitted to humans through hand-to-mouth transmission of the tapeworm eggs from dog faeces causing echinococcosis due to *Echinococcus granulosus*, or cystic hydatid disease. Such high-risk dogs should periodically receive antihelminth treatment with a chemotherapeutic agent such as praziquantel (Biltricide®).

Control measures applied to the environment

Control measures applied to the environment are designed to interrupt the routes of transmission by which an infectious agent may be spread through the environment. Just as the routes of transmission are varied, so, too, are the control methods that can be applied. Control measures that affect transmission that can be applied to the host, agents, vectors, infected humans, and other animals are reviewed elsewhere in this chapter. Environmental factors may also have a direct impact on the host, agent, or vector. For example, low humidity may predispose to certain infections due to a greater permeability of mucous membranes in the host; cold, dry climates inhibit development of the infective larvae agent of hookworm disease; and higher altitudes and colder climates limit the mosquito vector.

The recognition of the relationship between disease and filth led to a sanitary revolution in industrialized countries that markedly reduced infectious diseases even before the arrival of the antibiotic era. Improved methods for storing and preserving food, better housing, and smaller families with a resultant decrease in the risk of infections at an early age all contributed to reductions in infant and child mortality rates.

This section focuses on general environmental control measures not mentioned elsewhere. Some of these methods, such as provision of safe water, have the potential to prevent several different infectious diseases and significantly reduce rates of disease in the community.

Provision of safe water

It has been estimated that some 783 million still lack safe drinking water in 2010 (WHO and United Nations Children's Fund 2012). Contaminated drinking water, sometimes the result of poorly designed or maintained systems of sewerage, may lead to the water-borne indirect transmission of such infectious agents as *Giardia lamblia* causing giardiasis, pathogenic serotypes of *Salmonella* causing salmonellosis, and *Cryptosporidium* species causing cryptosporidiosis.

Purification of water can occur through natural methods or human intervention. Examples of natural methods that contribute to water purification include the processes of evaporation and condensation, filtration through the earth, plant growth, aeration, and reduction and oxidation of organic material by bacteria. Purification of water for public consumption is conventionally done through such processes as coagulation of colloids by

aluminium salts or with other techniques; filtration through such materials as coal, sand, or diatomaceous earth; and disinfection with such chemicals as chlorine derivatives. In special situations, boiling and distillation can be used for purification (Solomon et al. 2009).

Proper disposal of faeces

It has been estimated that some 2.5 billion people in the developing world do not have an adequate system for proper disposal of faeces with some 1.1 billion people practising open defecation (WHO and United Nations Children's Fund 2012). Infectious agents in faeces that may result in infectious diseases include poliovirus causing poliomyelitis; *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei* causing shigellosis; and *Entamoeba histolytica* causing amoebiasis.

Infectious agents in faeces may be transmitted by the direct transmission route (including the faecal–oral mode), the vehicle-borne route (including water as noted in the previous section), and the vector-borne route (including the simple mechanism of flies carrying infected faeces on their feet). Public health environmental control measures to interrupt these routes of transmission by ensuring the proper disposal of faeces include the following:

- ◆ Appropriate on-site disposal through such means as properly constructed sanitary privies in rural areas with no sewerage systems.
- ◆ On-site disposal of domestic wastewater (such as use of septic tanks or cesspools).
- ◆ Sewerage systems with treatment of wastewater. Such treatment may include preliminary treatment, sedimentation, chemical coagulation and flocculation, biological treatment (such as activated sludge units and trickling filters), stabilization ponds, sludge management, and disinfection (usually with chlorine) of effluents discharged into drinking, bathing or shellfish-growing waters.

The importance of personal health-promoting behaviours of using toilets, keeping toilets clean, and hand washing after defecation are a part of control efforts aimed at the proper disposal of faeces.

Food sanitation

Food-borne infectious diseases remain a problem in both industrialized and developing countries. In the United States in 2011 alone, it is estimated that some 48 million people became ill, 128,000 were hospitalized, and 3000 died of foodborne-related diseases (CDC 2012a). Significant food-borne outbreaks and sporadic cases continue to occur due to such factors as the following:

- ◆ Contamination of meat, poultry, and eggs with infectious agents, including pathogenic serotypes of *Salmonella*, *Yersinia pseudotuberculosis* and *Yersinia enterocolitica*, and *Listeria monocytogenes*.
- ◆ Contamination of vegetables, especially lettuce and leafy green vegetables, with the infectious enterohaemorrhagic strain of *Escherichia coli* O157:H7. Other outbreaks in fruits, juices, and vegetables have been due to contamination with hepatitis A and pathogenic serotypes of salmonella.
- ◆ Problems in food storage, handling, and preparation in commercial eating places and in homes.

- ◆ Larger and more centralized production and processing facilities, coupled with increasingly extensive distribution networks, which may result in transmission of infectious agents to many people if a commercial product becomes contaminated.

Industrialized countries have significantly reduced the transmission of some infectious agents through major public health programmes in food sanitation, including: (1) inspecting eating and drinking establishments, (2) inspecting meat and poultry, (3) improving shellfish sanitation, and (4) promoting adequate cooking, canning, and refrigeration methods. Some cities and counties have instituted restaurant grading systems based on inspection reports, including required public display of the restaurant's grade as a guide for consumers.

Examples of vehicle-borne indirect transmission of infectious agents through food that can be controlled through a comprehensive public health food sanitation programme include the following:

- ◆ Pathogenic serotypes of *Salmonella* transmitted by ingesting food made from infected animals or contaminated by the infectious agent in faeces that may cause salmonellosis. Methods of control—preventive measures: 'a) handwashing before, during and after food preparation; b) refrigerating prepared foods in small containers; c) thoroughly cooking all foodstuffs derived from animal sources, particularly poultry, pork, egg products and meat dishes; d) avoiding recontamination within the kitchen after cooking is completed; and e) maintaining a sanitary kitchen and protecting prepared foods against rodent and insect contamination' (Heymann 2010).
- ◆ *Staphylococcus aureus* causing staphylococcal food intoxication by ingesting food containing the staphylococcal enterotoxin. Methods of control—preventive measures: 'Reduce food-handling time (from initial preparation to service) to a minimum, no more than 4 hours at ambient temperature. If foods are to be stored for more than 2 hours, keep those that are perishable hot (above 60°C/140°F) or cold (below 5°C/41°F), in shallow containers, and covered.' 'Temporarily exclude people with boils, abscesses and other purulent lesions of hands, face or nose from food handling.' (Heymann 2010).
- ◆ *Trichinella spiralis* transmitted by ingesting raw or improperly cooked meat or meat products, mainly pork, containing infectious encysted larvae that may cause trichinosis. Methods of control—preventive measures:
 1. Educate the public on the need to cook all fresh pork and pork products and meat from wild animals at a temperature and for a time sufficient to allow all parts to reach at least 71°C (160°F), or until meat changes from pink to grey, which allows a sufficient margin of safety. This should be done unless it has been established that these meat products have been processed either by heating, curing, freezing or irradiation adequate to kill trichinae.
 2. Grind pork in a separate grinder, or clean the grinder thoroughly before and after processing other meats.
 3. Adopt regulations to encourage commercial irradiation processing of pork products. Testing carcasses for infection with a digestion technique is useful, as is immunodiagnosis of pigs with an approved ELISA test.
 4. Adopt and enforce regulations that allow only certified trichinea-free pork to be used in raw pork products that have a cooked appearance, or in products that are traditionally not heated sufficiently in final preparation to kill trichinae.
 5. Adopt laws and regulations to require and enforce the cooking of garbage and offal before feeding to swine. (Heymann 2010).

Milk sanitation

Milk may be a vehicle for indirect transmission of such infectious agents as: *Mycobacterium bovis* causing tuberculosis, *Corynebacterium diphtheriae* causing diphtheria, *Listeria monocytogenes* causing listeriosis, and *Campylobacter jejuni* and *Campylobacter coli* causing *Campylobacter* enteritis.

Public health control measures to break the chain of transmission of infectious agents through milk include:

- ◆ Mechanization and sanitization of milking processes.
- ◆ Refrigeration of milk to inhibit bacterial growth.
- ◆ Pasteurization of milk through high-temperature short-time, batch, ultra-pasteurization, or ultra-high-temperature methods that help to kill any bacteria from the cow or others that may have come into direct contact with milk during the milking and handling process.
- ◆ Monitoring milk quality by testing for bacteria using a standard bacterial plate count, by testing for density of coliform organisms, and by use of the phosphatase test to assay for pasteurization.
- ◆ Periodically testing cows for tuberculosis and brucellosis.

The use of raw milk for human consumption may result in outbreaks. A study showed that some 60 per cent of dairy-related outbreaks reported to the CDC between 1993 and 2006 were associated with raw milk products (CDC 2012b). It should be noted that post-pasteurization contamination of milk may also result in outbreaks of milk-borne diseases.

Design of facilities and equipment

The design and proper maintenance of buildings, rooms, and equipment can help break the chain of transmission of infectious agents. Laminar airflow hoods in laboratory workbenches, ventilation systems in hospitals, and disposable intravenous equipment are examples of systems designed to reduce risk of transmission. Routine maintenance needed to retain the original design standards for control of transmission of infectious agents include: (1) replacement of air filters, (2) cleaning of cooling towers, (3) monitoring of positive pressure rooms and airlocks, and (4) replacement of in-dwelling peripheral venous catheters.

Examples of infectious agents whose transmission can be reduced through proper design and maintenance include the following:

- ◆ *Legionella* species, the infectious agents responsible for legionellosis, are usually transmitted through airborne transmission via aerosol production. Transmission of the agent from cooling towers can be reduced by periodically cleaning off any scale or sediment, routinely using biocides to kill slime-forming organisms, and draining such towers when not in use.

- ◆ *Staphylococcus aureus*, the infectious agent responsible for staphylococcal disease in medical and surgical wards of hospitals, can be controlled by enforcing strict aseptic technique, including procedures to change intravenous infusion sites at least every 48 hours and replace indwelling peripheral venous catheters every 72 hours.
- ◆ *Bacillus anthracis*, the infectious agent responsible for anthrax, can be transmitted, among other ways, through inhalation of anthrax spores. Proper design of industrial plants that handle raw animal fibres include providing facilities for adequate ventilation and control of dust, washing and changing clothes after work, and eating away from the places of work.

Other methods

In addition to the environmental methods of control of transmission of infectious agents already mentioned, the following are other methods, some specific and some general, that should also be noted.

- ◆ Improvement of housing conditions to *reduce crowding* (as measured by the number of people per room and not total population density). Reduction in crowding is a general measure that can reduce the transmission of infectious agents, especially direct transmission from direct contact or direct projection (droplet spray).
- ◆ *Improvement in working conditions* can affect the risk of infectious disease. For example, control of particulate matter by proper ventilation in occupations such as textile mill workers, metal grinders, and pottery factory workers can reduce inflammation of the lungs and thus decrease the risk of developing tuberculosis. Excessive physical exertion and the stress of exhausting work can also increase the risk of tuberculosis.
- ◆ Improved *irrigation* and agricultural practices and *removing vegetation or draining and filling* of snail-breeding sites can reduce or eliminate the freshwater snail hosts of such infectious agents as *Schistosoma mansoni*, *Schistosoma haematobium* and *Schistosoma japonicum* that cause schistosomiasis in humans.
- ◆ *Adequate screening* of blood, serum, plasma, tissues, or organs can break the chain of vehicle-borne transmission from such biological products. Examples include screening for hepatitis B surface antigen and HIV antibodies in donated blood to prevent transmission of hepatitis B and HIV, respectively.
- ◆ Installation of *screened living and sleeping quarters* and use of *bednets*, including bednets impregnated with a synthetic pyrethroid such as permethrin, can reduce exposure to mosquitoes infected with the infectious agents of malaria.

Control measures applied to the agent

Control of some infectious diseases can be achieved through means that remove the infectious agents from the environment or inactivate the agents. Physical measures (such as heat, cold, ultraviolet light, and ionizing radiation) and chemical measures (such as liquid disinfectants and antiseptics, gases, and chlorination)

can be used. Examples of control measures applied to infectious agents include the following:

- ◆ *Cleaning* is the removing of infectious agents from surfaces through such physical actions as vacuum cleaning or washing and scrubbing using soap or detergent and hot water. Cleaning also helps remove organic materials that might support the growth or survival of infectious agents.
- ◆ *Cooling* may inhibit bacterial multiplication and some infectious agents, such as *Trichinella* cysts and *Taenia solium* larvae (cysticerci), can be killed by freezing temperatures.
- ◆ *Pasteurization* is heating to a temperature of 75°C/167°F for 30 minutes to kill pathogenic vegetative bacteria. It does not inactivate bacterial spores. Pasteurization is a commonly used process to help ensure safety of milk and to prolong its storage quality.
- ◆ *Disinfection* is the reduction or killing of vegetative harmful bacterial infectious agents outside the body or on objects. Disinfection may not inactivate all bacterial spores and viruses. *Disinfectants* are used to eliminate pathogenic bacteria from the skin surface and from contaminated inanimate surfaces and include: (1) alcohols, (2) halogens such as iodine and chlorine, (3) surface active compounds such as the quaternary ammonium compound benzalkonium chloride, (4) phenolics, and (5) alkylating agents such as glutaraldehyde and formaldehyde. *Antiseptics* are a class of disinfectant that can be applied on body surfaces; they have a lower toxicity than environmental disinfectants and are usually less effective in killing microorganisms.
- ◆ *Sterilization* is the complete removal or killing of all infectious agents in, or on, an object. Sterilization of equipment for surgery and wound dressings; parenteral administration of drugs, vaccines or nutrients; catheterization; and dental work are all important means of controlling infectious diseases by killing infectious agents. Sterilization can be accomplished through use of fire, steam (such as in an autoclave), heated air, certain gases (such as ethylene oxide), ultraviolet light, ionizing radiation, liquid chemicals, and filtration. The method of sterilization chosen depends on the type of equipment to be sterilized.

The use of sterilized *disposable equipment*, such as disposable needles, syringes, and catheters, has the potential to reduce the risk of transmission of infectious agents. However, it must be assured that such equipment is disposed of properly and is not reused. For example, disposable syringes cannot be properly resterilized because the plastic from which they are made cannot withstand the heat necessary for sterilization. Technologies, such as the single-use disposable needle and syringe developed for immunization programmes, help assure such disposable equipment is not reused.

Control and prevention programmes

The preceding sections have considered the issues and given examples of control measures for infectious diseases at individual, institutional, and community levels and the tools for control directed at the host, routes of transmission, and the agent. Control and prevention programmes using these tools must be developed according to a number of factors including: (1) the risk of disease; (2) the magnitude of disease burden (as measured by mortality,

degree of disability, morbidity, and economic costs); (3) the feasibility of control strategies; (4) the cost of control measures; (5) the effectiveness of such measures (on current levels of disease and impact on future cases or outbreaks); (6) the adverse effects or complications of the control measures; and (7) the availability of resources. Public health planning for the control of infectious diseases must consider these issues to design optimal, evidence-based control and prevention programmes.

The tools of disease surveillance for recognition and evaluation of the patterns of disease can provide information on the risk and magnitude of disease burden to individuals, people in institutions, subgroups of populations, and the community at large. Establishment and maintenance of the infrastructure for surveillance, including a system for the reporting of notifiable infectious diseases and unusual events, must be a high priority.

Feasibility of possible control and prevention strategies must be assessed through operational research, pilot projects, or from field experience. The fact that a particular measure can help control a disease does not mean it can be applied on a sufficient scale to have the desired impact. The cost of control activities (in both human and material resources) can be assessed through costing studies that can also provide the data needed to conduct more rigorous cost-benefit and cost-effectiveness analyses. A costly measure, even if it provides a high degree of control for an infectious disease, may not be affordable to the society or reasonable to apply in the light of other less expensive alternative strategies. For example, use of sterile, disposable products may be more costly than reusable, sterilizable products. Effectiveness of control measures may be assessed through epidemiological studies to find out their impact on reduction in the incidence or prevalence of disease.

The availability of resources for prevention and control programmes forces public health planners to set priorities by taking into account all these factors and then designing programmes that have maximum impact within available resources. Planners have a responsibility to mobilize additional necessary resources by raising public awareness and generating political will. Effective communication of disease burden and the results achievable through well-managed and effective control programmes can be a powerful tool for advocacy. Ideally, communities or their representatives should actively participate in the planning, execution, and evaluation of public health programmes.

Prevention effectiveness is 'the measure of the impact on health (including effectiveness, safety and cost) of prevention policies, programmes, and practices. The assessment of prevention effectiveness is the ongoing process of applying evaluation tools to prevention practices' (CDC 1995). Recognizing that systems for assessing the effectiveness of prevention strategies (including prevention strategies for infectious diseases) are weak or non-existent in both developing and industrialized countries alike, the CDC has suggested the following objectives for prevention effectiveness activities: 'evaluate the impact of prevention, use results of evaluation research to establish programme priorities, and establish or apply standardized methods to compare the benefits and effectiveness of alternative prevention strategies' (CDC 1995).

The current situation of *international migration* of many people worldwide presents an additional complexity to the design of programmes for the control of infectious diseases. Pertinent issues include refugee camps, legal status of migrants in recipient countries, and temporary return migration. Public health officials

must consider the most effective mix of combined control measures applied to the host, agent, and routes of transmission when designing suitable control and prevention programmes (Gellert 1993).

International commerce and transportation are important areas of concern for public health infectious disease control programmes, especially as the speed of travel has increased. The tools of control include such measures as:

- ◆ Spraying insecticides effective against mosquito vectors of malaria in aircraft before departure, in transit, or on arrival.
- ◆ Rat-proofing or periodic fumigation to control rats on ships, docks, and warehouses to prevent plague.

Specific international control measures relating to aircraft, ships, and land transportation for infectious diseases are detailed in the *International Health Regulations (2005)* (WHO 2005).

The challenge facing infectious disease control programmes is to design an optimal set of interventions at local, institutional, community, national, and international levels supported and accepted by the political leadership and the people to whom these measures are applied.

Eradication

A unique end point in the control of infectious diseases is that of eradication. Eradication is the cessation of all transmission of an infectious agent by extermination of that agent. To date, only one human infectious disease, *smallpox*, and one animal infectious disease, rinderpest, have been eradicated. The WHO World Health Assembly in May 1980 confirmed its global eradication some 3 years after the last naturally acquired case of smallpox in October 1977 (Fenner et al. 1988). The magnitude of this accomplishment is appreciated when one realizes that, in the early 1950s, it was estimated that 50 million cases of smallpox still occurred each year in the world, some 150 years after Edward Jenner had performed the first vaccination and wrote: 'it now becomes too manifest to admit of controversy, that the annihilation of the Small Pox, the most dreadful scourge of the human species, must be the final result of this practice' (Fenner et al. 1988). Rinderpest (known as cattle plague or steppe murrain) was an infectious viral disease of cattle and some other even-toed ungulates, that was associated with a high mortality rate. In 2011, after widespread vaccination campaigns, the United Nations declared the disease eradicated.

The goal of global eradication has been set by the World Health Assembly for two other infectious diseases, poliomyelitis caused by wild poliovirus and dracunculiasis (Guinea worm infection), the latter caused by the infectious agent *Dracunculus medinensis*. A high level of sustained political will, aggressively applied disease surveillance, and effective control measures are the required elements to achieve eradication of the infectious agents for these diseases.

Impressive progress has been made towards the global *eradication of poliomyelitis* since the 1988 World Health Assembly set the goal for its eradication. Polio cases have decreased by over 99 per cent since that date, from some 350,000 cases in over 125 countries to only 650 reported cases in 2011. In 2012, only parts of three countries in the world (Nigeria, Pakistan, and Afghanistan) remain endemic for the disease (WHO 2012c). Poliomyelitis

control measures that will lead to eradication include the following:

- ◆ Achieving and maintaining high levels of routine coverage of infants with at least three doses of oral polio vaccine.
- ◆ Mass application of oral polio vaccine in countries where poliomyelitis is endemic through national immunization days, usually by providing oral polio vaccine to every child less than 5 years of age twice each year, separated by 4–6 weeks, and conducted during the low season of poliovirus transmission.
- ◆ ‘Mopping-up’ operations after the use of national immunization days has reduced transmission of disease to defined focal geographic areas, usually by providing oral polio vaccine house-to-house to all children less than 5 years of age on two occasions separated by 4–6 weeks.
- ◆ Aggressive action-oriented surveillance for acute flaccid paralysis. Such surveillance includes: (1) case investigation, (2) a laboratory network for isolation and characterization of polioviruses in suspect cases of poliomyelitis and people in close contact with them, and (3) limited outbreak response immunization providing one house-to-house round of oral polio vaccine to children less than 5 years of age living in the same village or neighbourhood of the patient.

Significant strides in the *eradication of dracunculiasis* have also been made. Over the last decade the total number of dracunculiasis cases has declined by more than 95 per cent. In 2010, fewer than 1800 cases were reported and, by 2011, the disease was limited to only certain areas of sub-Saharan Africa. Dracunculiasis control measures that are leading to its ultimate eradication include the following:

- ◆ Establishing a national programme office, conducting baseline surveys, and preparing and refining a national plan of action.
- ◆ Educating the population in endemic areas that the source of Guinea worm comes from their drinking water.
- ◆ Ensuring that people with blisters or emerging worms do not enter sources of drinking water through behaviour changes and by converting step-wells into draw-wells.
- ◆ Promoting the boiling or filtering of water through a fine mesh cloth to remove copepods. Treating drinking water with chlorine or iodine will also kill the copepods and infective larvae.
- ◆ Providing non-infected water through construction of wells or rainwater catchments.
- ◆ In selected endemic villages, controlling copepod populations with temephos (Abate®) insecticide placed in reservoirs, tanks, ponds, and step-wells.
- ◆ Implementing an intensified surveillance and aggressive case-containment strategy as programmes get close to achieving eradication.

The eradication of a disease requires a unique set of conditions, including the following: (1) a defined, accessible reservoir of the infectious agent; (2) affordable and effective control measures that can interrupt the chain of infection directed at the host, agent, or route of transmission; and (3) a surveillance mechanism adequate to monitor and ultimately certify the disappearance of the infectious agent.

It is likely that measles may be targeted for global eradication in the future. Some countries and geographic regions have already targeted measles for elimination—a term sometimes used to describe the eradication of a disease from a large geographic area. Other diseases that may potentially be targeted for eradication in the future include: mumps, rubella, hepatitis B, leprosy, and diphtheria.

Emerging infectious diseases

New, emerging and re-emerging infectious diseases have become a focus for the attention of public health prevention and control programmes in both industrialized and developing countries. Such infectious diseases have thwarted any expectation that infectious diseases will soon be eliminated as public health problems and resulted in a widening spectrum of diseases, many of which were once thought to be almost conquered. Krause has reflected on this as follows:

Bacteria reproduce every 30 minutes. For them, a millennium is compressed into a fortnight. They are fleet afoot, and the pace of our research must keep up with them, or they will overtake us. (Krause 1998)

Many factors contribute to the emergence of new or re-emergence of those previously known (Lederberg et al. 1992; CDC 1994; Murphy 1994), including the following:

- ◆ *Human demographic change* by which people begin to live in previously uninhabited remote areas of the world and are exposed to new environmental sources of infectious agents, insects, and animals.
- ◆ *Breakdowns of sanitary and other public health measures* in overcrowded cities and in situations of civil unrest and war.
- ◆ *Economic development and changes in the use of land*, including deforestation, reforestation, and urbanization.
- ◆ *Climate change*, including global warming, which may extend the favourable habitats for vectors such as mosquitoes.
- ◆ *Other human behaviours*, such as increased use of child-care facilities, sexual and drug use behaviours, and patterns of outdoor recreation.
- ◆ *International travel and commerce* that quickly transport people and goods vast distances.
- ◆ *Changes in food processing and handling*, including foods prepared from many different individual animals and transported great distances.
- ◆ *Evolution of pathogenic infectious agents* by which they may infect new hosts, produce toxins, or adapt by responding to changes in the host immunity.
- ◆ *Development of resistance of infectious agents* such as *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae* to chemoprophylactic or chemotherapeutic medicines.
- ◆ *Resistance of the vectors* of vector-borne infectious diseases to pesticides.
- ◆ *Immunosuppression of people* due to medical treatments or new diseases that result in infectious diseases caused by agents not usually pathogenic in healthy hosts.
- ◆ *Deterioration in surveillance systems* for infectious diseases, including laboratory support, to detect new or emerging disease problems at an early stage.

Examples of emerging infectious disease threats include the following:

- ◆ Toxic shock syndrome, due to the infectious toxin-producing strains of *Staphylococcus aureus*, illustrates how a new technology yielding a new product, super-absorbent tampons, can create the circumstances favouring the emergence of a new infectious disease threat.
- ◆ Lyme disease, due to the infectious spirochete *Borrelia burgdorferi*, illustrates how changes in the ecology, including reforestation, increasing deer populations, and suburban migration of the population, can result in the emergence of a new microbial threat that has now become one of the most prevalent vector-borne disease in the United States.
- ◆ Shigellosis, giardiasis, and hepatitis A are examples of emerging diseases that have become threats to staff and children in child-care centres as the use of such centres has increased due to changes in the work patterns of societies.
- ◆ Opportunistic infections, such as pneumocystis pneumonia caused by *Pneumocystis jirovecii* (formerly *carinii*), chronic cryptosporidiosis caused by *Cryptosporidium* species, and disseminated cytomegalovirus infections, illustrate emerging disease threats to the increasing number of people who are immunosuppressed because of cancer chemotherapy, organ transplantation, or HIV infection.
- ◆ Foodborne infections such as diarrhoea caused by the enterohaemorrhagic strain O157:H7 of *Escherichia coli* and waterborne infections such as gastrointestinal disease due to *Cryptosporidium* species are examples of emerging disease threats that have arisen due to such factors as changes in diet, food processing, globalization of the food supply, and contamination of municipal water supplies.
- ◆ Hantavirus pulmonary syndrome first detected in the United States in 1993 and caused by a previously unrecognized hantavirus illustrates how exposure to certain kinds of infected rodents can result in an emerging infectious disease.
- ◆ Nipah virus disease first detected in Malaysia in 1999 and caused by a previously unrecognized Hendra-like virus demonstrates how close contact with fruit bats and pigs can result in an emerging infectious disease.
- ◆ Severe acute respiratory syndrome (SARS), a viral respiratory illness caused by the SARS-associated coronavirus (SARS-CoV) that was first reported in Asia in February 2003 and spread to more than 20 countries in North America, South America, Europe, and Asia affecting over 8000 people and killing over 700 before the SARS global outbreak was contained in 2004, shows the need for continued vigilance in surveillance and outbreak response capacity.
- ◆ The emergence of the novel influenza A virus in birds, highly pathogenic avian influenza (H5N1), that has occasionally infected humans is an example of an antigenic shift in an influenza virus that, should it develop into a form easily transmissible from human to human, could potentially lead to a pandemic.

Antimicrobial drug resistance as a major factor in the emergence and re-emergence of infectious diseases deserves special attention. Although significant reductions in infectious disease mortality

have occurred since the introduction of antimicrobials for general use in the 1940s, antimicrobial drug resistance has emerged because of their widespread use in humans.

Drugs that once seemed invincible are losing their effectiveness for a wide range of community-acquired infections, including tuberculosis, gonorrhoea, pneumococcal infections (a leading cause of otitis media, pneumonia, and meningitis), and for hospital-acquired enterococcal and staphylococcal infections. Resistance to antiviral (e.g. amantadine-resistant influenza virus and aciclovir-resistant herpes simplex), antifungal (e.g. azole-resistant *Candida* species), and antiprotozoal (e.g. metronidazole-resistant *Trichomonas vaginalis*) drugs is also emerging. Drug-resistant malaria has spread to nearly all areas of the world where malaria occurs. Concern has also arisen over strains of HIV resistant to antiviral drugs. Increased microbial resistance has resulted in prolonged hospitalizations and higher death rates from infections; has required much more expensive, and often more toxic, drugs or drug combinations (even for common infections); and has resulted in higher health care costs (CDC 1994).

Antimicrobial drug resistance has also emerged because of the use of antimicrobials in domesticated animals. For example, the use of fluoroquinolones in poultry has created a reservoir of quinolone-resistant *Campylobacter jejuni* that has now been isolated in humans.

An aggressive public health response to these new, emerging and re-emerging infectious disease threats must be made to characterize them better and to mount an effective response for their control. For example, the 1999 outbreak of West Nile fever in New York City and surrounding areas that, within a 4-year period, spread throughout the United States demonstrates how a viral encephalitis, initially classified as Saint Louis encephalitis and later confirmed to be due to West Nile virus, can reach far beyond its normal setting.

The WHO has outlined the following high-priority areas (WHO 1995):

- ◆ Strengthen global surveillance of infectious diseases.
- ◆ Establish national and international infrastructures to recognize, report, and respond to new disease threats.
- ◆ Further develop applied research on diagnosis, epidemiology, and control of emerging infectious diseases.
- ◆ Strengthen the international capacity for infectious disease prevention and control.

Emerging infectious diseases are addressed in detail in Chapter 8.17.

Bioterrorism: the deliberate use of biological agents to cause harm

Another unfortunate source of an infectious disease threat is the spectre of biological warfare or bioterrorism, especially in an age where terrorist acts are frequent events (Christopher et al. 1997). The 2002 World Health Assembly resolution urges member states 'to treat any deliberate use, including local, of biological and chemical agents and radionuclear attack to cause harm also as a global public health threat, and to respond to such a threat in other countries by sharing expertise, supplies and resources in

order rapidly to contain the event and mitigate its effects' (WHO 2002).

The WHO recommends the following (WHO 2004):

- ♦ Public health authorities, in close cooperation with other government bodies, should draw up contingency plans for dealing with a deliberate release of biological or chemical agents intended to harm civilian populations. These plans should be consistent or integral with existing plans for outbreaks of disease, natural disasters, large-scale industrial or transportation accidents, and terrorist incidents.
- ♦ Preparedness for deliberate releases of biological or chemical agents should be based on standard risk-analysis principles, starting with risk and threat assessment in order to determine the relative priority that should be accorded to such releases in comparison with other dangers to public health in the country concerned. Considerations for deliberate releases should be incorporated into existing public health infrastructures, rather than developing separate infrastructures.
- ♦ Preparedness for deliberate releases of biological or chemical agents can be markedly increased in most countries by strengthening the public health infrastructure, and particularly public health surveillance and response, and measures should be taken to this end.
- ♦ Managing the consequences of a deliberate release of biological or chemical agents may demand more resources than are available, and international assistance would then be essential.

Many countries are developing rapid response capability to deal with such contingencies, especially in the light of the 2001 bioterrorist attack using anthrax in the United States.

Conclusion

Only through worldwide concerted action will the effort to control infectious disease be effective. We are now in an era where, as Nobel Laureate Dr Joshua Lederberg has stated, 'The microbe that felled one child in a distant continent yesterday can reach yours today and seed a global pandemic tomorrow' (quoted in CDC 1994). As Hans Zinsser stated over 60 years ago:

Infectious disease is one of the few genuine adventures left in the world. The dragons are all dead and the lance grows rusty in the chimney corner... About the only sporting proposition that remains unimpaired by the relentless domestication of a once free-living human species is the war against those ferocious little fellow creatures, which lurk in the dark corners and stalk us in the bodies of rats, mice and all kinds of domestic animals; which fly and crawl with the insects, and waylay us in our food and drink and even in our love. (Hans Zinsser 1934, quoted in Murphy 1994)

Population screening and public health

Allison Streetly and Lars Elhers

Introduction to population screening and public health

The concept of screening, with the active identification of a disease or pre-disease condition in individuals who presume themselves to be healthy but may benefit from early treatment, sounds easy and attractive. The presumption is that if this is done, the clinical course of the disease will be altered and prognosis improved. Unfortunately, the reality of screening is more difficult and screening programmes, like other healthcare interventions, may do harm (Raffle and Gray 2007). Unlike most other healthcare interventions, screening programmes are offered to individuals who consider themselves to be healthy and the harms caused by screening programmes are therefore particularly difficult to accept. Consequently, it is important to appreciate what the potential benefits and harms of screening may be, the conditions required for a cost-effective programme, and why the public may favour screening whilst policymakers may not. Public health scientists and practitioners contribute by providing and appraising evidence concerning the benefits and harms of screening, managing screening programmes, and informing the expectations of the public and other stakeholders. This chapter outlines the principles that underpin the development and implementation of screening programmes. It also provides a brief summary of screening applications at different stages of life.

Development of screening as a concept

Historical development

The potential benefits of screening were first demonstrated by the use of mass miniature radiography (MMR) for the identification of individuals with tuberculosis (TB), and became common in many countries after effective TB treatment became available from 1946. Subsequently, screening was considered for other chronic conditions especially in the United States, where a law on the control of chronic diseases and the availability of screening was passed in the late 1950s. Wilson from the United Kingdom worked with Jungner, a Swedish biochemist, to develop suggested criteria which should be met before a screening programme is adopted (Wilson and Jungner 1968).

In the past 50 years, professional attitudes towards screening have changed by the appreciation that screening also has disadvantages and should only be introduced for certain defined conditions

and in carefully controlled circumstances (Holland and Stewart 1990, 2005). By contrast, despite widely quoted mishaps, screening has become much more popular with the general public. In recent years, especially in high-income countries, the population has become more health conscious and, with the growth of the Internet, knowledgeable about health matters. This has increased the demand for health interventions. A firm belief has developed that the earlier a diagnosis is made, the better will be the outcome. This belief in the efficacy of screening is fuelled through the advocacy of charities concerned with individual diseases, by private clinics and providers who may have good intentions but also a profit motive, and by some doctors and politicians anxious to publicize their belief in the value of prevention. Screening has become a commercial enterprise, in terms of the promoting as well as the supply of reagents and equipment. It has in some cases become driven by financial incentives to promote unproven tests and services, for example, in the form of mobile screening units in supermarkets. Governments are often willing to 'invest' in screening services, even at relatively high cost and with relatively small benefits, as, for example, in screening for breast cancer, in order to show that they care. Critics who advocate caution in particular instances have been undermined or attacked (Holland and Stewart 1990, 2005).

Concepts in screening

Definitions of screening

McKeown (1968) defined screening as 'medical investigation which does not arise from a patient's request for advice for a specific complaint'. This definition of screening may encompass: (1) research for the validation of a procedure; or (2) tests done for public health reasons, for example, to identify the source of infection in a food outbreak; or (3) as a direct contribution to the health of the individual. It is this last, prescriptive screening, which is now the most common objective. There have been a number of modifications of this definition since 1968. The UK National Screening Committee (2000) (now part of Public Health England) defined screening as 'a public health service in which members of a defined population, who do not necessarily perceive that they are at risk of, or are already affected by, a disease or its complications are asked a question or offered a test to identify those individuals who are more likely to be helped than harmed by further tests or treatment to reduce the risk of disease or its complications'.

Clinical practitioners commonly misuse use the term ‘screening’ when they systematically apply tests to their existing patients to detect evidence of elevated risks or early-stage complications as, for example, when diabetic patients are examined annually for signs of retinal disease or peripheral nerve damage. The term ‘screening’ is also used inappropriately when individuals are offered tests non-systematically, as when they are tested for infectious diseases. These approaches are more correctly termed ‘testing’ (Gostin 2000) or ‘opportunistic screening’ or ‘case finding’. The term ‘screening’ should only be used when populations, or groups of people who are thought to be at risk, are systematically offered screening tests as in national programmes for cancer of the breast and cervix.

Benefits and disadvantages

It is essential to recognize both the benefits and possible harms of screening for individuals and populations (Table 11.4.1) (Chamberlain 1984; Raffle and Gray 2007). Questions of over-diagnosis and/or overtreatment are relevant to most population screening programmes. If thousands of tests are done, ‘errors’ are bound to occur and some individuals incorrectly labelled, particularly if programmes are not subjected to stringent continuing quality control. Such individuals may become stigmatized and anxious, while others are falsely reassured. Thus the ethics of screening are important. Cochrane and Holland (1971) emphasized that screening differs from most other forms of healthcare in that it is the healthcare provider who offers the intervention (often a test) with the implicit promise that undergoing this test may provide benefit. Hence, prevention programmes such as screening should only be introduced if they are likely on balance to do more good than harm to the particular population if the relevant principles and criteria are met. In many countries, national and professional bodies have published the tests and conditions for which screening must be justified, often with appropriate reviews. The United Kingdom provides a model approach in the form of the UK National Screening Committee, which is responsible for the review and ongoing assessment of screening. Equally important, but often done in a less structured way, is the evaluation and review of screening programmes throughout their life which may include the decision to stop an existing programme, for example, when the prevalence of a condition declines or alternative approaches to prevention are developed (e.g. human papilloma virus (HPV) vaccine for cervical cancer).

Considerations when implementing a screening programme

The criteria for introducing a screening programme provide a framework for ensuring that all the key issues are considered and appropriately evidenced. Many of the criteria are self-evident such as ‘the condition being an important health problem’ although there is an inevitable subjectivity to such criteria in terms of what is considered ‘important’. Test performance and cost-effectiveness are two of the key criteria and these are discussed further in the following subsections.

Criteria for introducing a screening programme

Before the introduction of screening for a condition, certain basic criteria should be fulfilled. The widely accepted criteria proposed by Wilson and Jungner (1968) served as the basis for a more elaborate set listed in the UK National Screening Committee’s Second Report (2000) (Box 11.4.1). Similar lists have been proposed by other countries and the World Health Organization (Andermann et al. 2008). These criteria require continuing review with advances in knowledge. For example, in the United Kingdom, recent amendments were made to take account of genetic screening (UK National Screening Committee 2000, n.d.) and there is currently a proposal to consider very rare conditions that might be detected in the newborn period, where the requirement to obtain strong evidence from randomized controlled trials (RCTs) is not considered ethical or feasible.

Consideration of the performance of a screening test

A key consideration listed in the earlier-mentioned criteria is the performance of the test. There are specific ways in which the performance of tests should be assessed before a decision to introduce screening is made. These are described in the following subsections.

Properties of screening tests

Screening tests must be applied to large numbers of healthy individuals, most of whom will be identified as screen negative. This means that screening tests must be evaluated in low-prevalence settings and not just in the high-prevalence settings, like hospitals,

Table 11.4.1 Potential benefits and disadvantages of screening programmes

Benefits	Disadvantages
Improved prognosis for some cases detected	Longer morbidity for cases whose prognosis is not altered
Less radical treatment which cures some early treated cases	Over-treatment of questionable abnormalities
Resource savings	Resource costs
Reassurance for those with negative test results	False reassurance for those with false negative results
	Anxiety and sometimes morbidity for those with false positive results
	Hazards of screening test itself, for example exposure to radiation

Box 11.4.1 UK National Screening Committee (2000) criteria for adopting a screening programme

Ideally, all the following criteria should be met before screening for a condition is initiated:

1. The condition should be an important health problem.
2. The epidemiology and natural history of the condition, including development from latent to declared disease, should be adequately understood, and there should be a detectable risk factor, disease marker, latent period, or early symptomatic stage.
3. All the cost-effective primary prevention interventions should have been implemented as far as practicable.
4. If the carriers of a mutation are identified as a result of screening, the natural history of people with this status should be understood, including the psychological implications.
5. There should be a simple, safe, precise, and validated screening test.
6. The distribution of test values in the target population should be known, and a suitable cut-off level defined and agreed.
7. The test should be acceptable to the population.
8. There should be an agreed policy on the further diagnostic investigation of individuals with a positive test result and on the choices available to those individuals.
9. If the test is for mutations, the criteria used to select the subset of mutations to be covered by screening, if all possible mutations are not being tested, should be clearly set out.

The treatment

10. There should be an effective treatment or intervention for patients identified through early detection, with evidence of early treatment leading to better outcomes than late treatment.
11. There should be agreed evidence-based policies covering which individuals should be offered treatment and the appropriate treatment to be offered.
12. Clinical management of the condition and patient outcomes should be optimized in all healthcare providers prior to participation in a screening programme.

The screening programme

13. There should be evidence from high-quality randomized controlled trials that the screening programme is effective in reducing mortality or morbidity.
14. There should be evidence that the complete screening programme (test, diagnostic procedures, treatment/intervention) is clinically, socially, and ethically acceptable to health professionals and the public.
15. The benefit from the screening programme should outweigh the physical and psychological harm.
16. The opportunity cost of the screening programme should be economically balanced in relation to expenditure on medical care as a whole (i.e. value for money).
17. There should be a plan for managing and monitoring the screening programme and an agreed set of quality assurance standards.
18. Adequate staffing and facilities for testing, diagnosis, treatment and programme management should be available prior to the commencement of the screening programme.
19. All other options for managing the condition should have been considered (e.g. improving treatment, providing other services).
20. Evidence-based information, explaining the consequences of testing, investigation, and treatment, should be made available to potential participants to assist them in making an informed choice.
21. Public pressure for widening the eligibility criteria for reducing the screening interval, and for increasing the sensitivity of the testing process, should be anticipated.
22. If screening is for a mutation, the programme should be acceptable to people identified as carriers and to other family members.

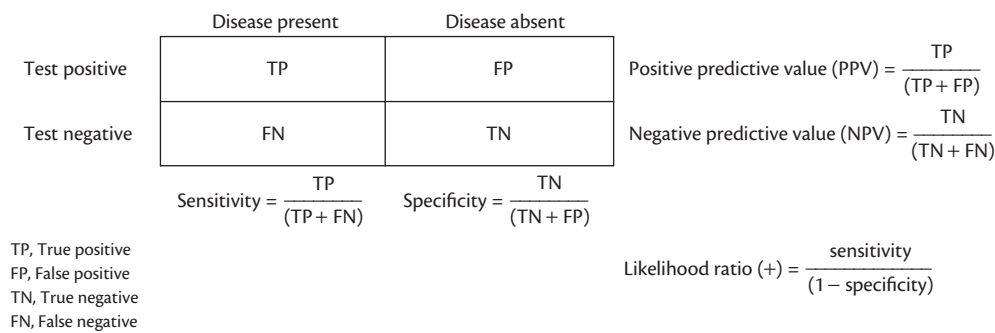

Fig. 11.4.1 Properties of a screening test.

where tests are often developed. Cochrane and Holland (1971) listed some desirable characteristics of screening tests including the requirement that they should be acceptable to screened subjects, safe, rapidly and easily applied, and not too costly.

The classification of individuals by screening test may be compared with the true disease status by a reference method or ‘gold standard’ (Fig. 11.4.1). Important characteristics to be assessed before any screening test can be considered for use in a screening programme include specificity and sensitivity. Specificity is defined as the proportion of disease-free subjects who are classified as true negatives by the test. Sensitivity is defined as the proportion of subjects with the condition of interest who are classified as true positives by the test. Ideally, both measures should be high. Clinicians commonly misperceive that high sensitivity is more important than specificity, in other words, a case must not be ‘missed’. In reality, all screening programmes will ‘miss’ some true positive cases and specificity is as, if not more, important for an effective and acceptable programme because high false-positive rates can outweigh the benefits to the few true positives identified, with negative consequences for individuals who test false positive. In particular, if the prevalence of the condition to be identified is low, it is important to realize that if the tests were developed in a high-prevalence setting, such tests are often not piloted on large enough numbers of unaffected individuals to be certain of the specificity with the degree of accuracy (sensitivity) required.

The positive predictive value of a test is the proportion of subjects with a positive test result who have the condition of interest. The positive predictive value is determined by the relative proportions of true positives and false positives and, with sensitivity and specificity remaining constant, the positive predictive value depends on the prevalence of the condition of interest. When the condition is common, true positives will be frequent but if the condition is rare, true positives will be infrequent. Conditions that are sought by screening programmes commonly have a prevalence lower than 1 per cent, consequently the positive predictive value of a screening test will be low unless both sensitivity and specificity are extremely high (Table 11.4.2). In practical terms, this means that false positive results may outnumber true positive results, and the impact of screening on those who do not have the condition of interest is an important concern, as has been the case in the debates concerning breast cancer screening.

As an example, a mean cell haemoglobin (MCH) of 27 pg is used as the cut-off in the detection of beta thalassaemia. This was shown to have a sensitivity of 100 per cent in a sample of 6314 results with 104 carriers from two London hospitals that serve a

Table 11.4.2 Positive predictive values (PPV) at different values for sensitivity and specificity and disease prevalence

Prevalence	PPV (%) if sensitivity = 75% and specificity = 75%	PPV (%) if sensitivity = 95% and specificity = 95%
10%	25.0	67.9
1%	2.94	16.1
0.1%	0.30	1.9
0.01%	0.03	0.2

high-prevalence population (Wald and Leck 2000). At this prevalence, the positive predictive value in this sample is approximately 77.4 per cent. In lower-prevalence areas, the predictive value of the same cut-point was estimated to range from 1.3 to 30 per cent depending on prevalence (National Health Service Sickle Cell and Thalassaemia Screening Programme n.d.). Using HbA2 estimation, in combination with the MCH result, to increase the specificity of the testing procedure, resulted in important reductions in the workload associated with follow-up of screen positives without compromising detection rate. Another example is the detection of maternal alpha zero carriers (who could be at risk of a hydrops fetus), where use of a MCH cut-off point of 25 pg gives a positive predictive value, in a research setting with results validated against DNA analysis, of 1:424 with 100 per cent sensitivity. Use of the MCH cut-point in combination with a question about family origins to increase specificity gives an estimated predictive value of 1:3 or 33 per cent (12/36) (Sorour et al. 2007). Applying this approach in practice reduces partner recall from 1:61 requiring follow up to 1:1497 requiring partner follow-up (a 96 per cent reduction in partner recall). These examples show how important the predictive value is as a measure of the impact of screening test on programme workload. They also demonstrate that when conditions are of low prevalence attending to the specificity of a test is extremely important if staff and public commitment to a programme are to be maintained.

When screening tests, such as biochemical markers, are quantitative, rather than a binary classification, the cut-off point used to separate ‘normal’ from ‘abnormal’ may be varied. A low cut-off point will give a high sensitivity but low specificity. As the cut-off point is increased the sensitivity decreases and specificity increases. Thus, there is a reciprocal relationship between

sensitivity and specificity. The area under the receiver operating characteristic (ROC) curve is used as a summary measure of test performance with the larger the area under the curve the better the test performance.

In general, the performance of a screening procedure may be improved by modifications that increase both sensitivity and specificity. This can sometimes be achieved by combining several tests together. Wald et al. (2003) compared combinations of two, three, or four biochemical measures in the antenatal detection of Down's syndrome. They reported that the 'double', 'triple', or 'quadruple' tests gave detection rates of 57, 62, and 70 per cent, respectively, while the odds of being affected given a positive result were 1:56, 1:52, and 1:45, respectively.

The likelihood ratio of a positive test provides another measure for assessing test performance. The post-test odds of disease are given by the product of the likelihood ratio of a positive test and the pre-test odds of disease. The likelihood ratio provides a measure of the relative increase in frequency of the disease in subjects who test positive compared with the untested population. The likelihood ratio of a positive test is given by sensitivity divided by $(1 - \text{specificity})$ (Fig. 11.4.1).

In summary, a screening test is not a diagnostic test. Instead, screening tests separate individuals into groups who have either a low or a high probability of disease being present. This is commonly misunderstood by members of the public who assume that a positive result is 'bad news' and a negative result means that 'all is clear'. This can result in considerable anxiety for the individuals who subsequently turn out to have a 'false positive result' if these perceptions are not addressed appropriately. A positive screening test result must usually be followed up by appropriate confirmatory tests to establish whether the screening result was a true positive, confirming the diagnosis and need for treatment, or more commonly that the result was a 'false positive' and the individual can be reassured. In addition, a good screening test will inevitably 'miss' some cases and this is difficult to communicate to the public and politicians and a challenge for committed professionals who often find this lack of perfection difficult to live with.

Cost-effectiveness and opportunity costs of screening

Screening programmes vary widely in purpose, process, and scope. Some population screening programmes are very costly, while others are relatively inexpensive. By definition, the implementation of any new population screening programme will require the allocation of scarce health resources—people, time, facilities, equipment, and knowledge—that could have been used for other purposes. The opportunity costs of implementing a new healthcare programme are the amount of health outcome forgone, for example, the quality-adjusted life years (QALYs) or disability-adjusted life years (DALYs) that could be gained by using the same resources on other healthcare activities instead. For this reason, explicit choices and prioritizations may be necessary. Evaluation, particularly health economic evaluation, seeks to inform decisions about the use of scarce resources in healthcare by estimating the 'value for money' of a programme (Drummond et al. 2007).

Different countries may apply slightly different criteria to evaluate the pros and cons of a population screening programme but

it is generally accepted that screening should be cost-effective (Andermann et al. 2008). Therefore, the decision to fund and implement a new screening programme should be informed by a pre-assessment of the marginal costs and effects of the programme compared to the best alternative(s).

The assessment for the introduction of a new population screening programme is, however, perhaps the most difficult type of health economic evaluation for multiple reasons. Firstly, the evaluation typically needs to be over a very long time horizon in order to capture the full clinical benefits of the programme. Because screening and early detection of illness may change the clinical course of the disease in the future, it is often necessary to include clinical evidence with a long follow-up period and lifetime modelling. Differences in timing raise a number of methodological questions such as discounting and extrapolation which add to the uncertainty (see Chapter 6.6). Studies with such a long follow-up may also be planned and conducted in a time and place that is very different from the situation in which the population screening is eventually introduced. For example, the RCTs of screening for abdominal aortic aneurysm (AAA) were planned and conducted in a time when there was less international focus and action on reducing smoking rates, and changes in societal values and norms over time, which made it difficult to predict whether or not the same results from RCTs of population screening would be obtainable several years later. In the case of AAA screening, the United Kingdom's recent experience has been that AAA prevalence rates are much lower than expected and therefore the pre-evaluation assumptions informing the cost-effectiveness modelling were based on out-of-date and high assumptions about prevalence (Choke et al. 2012).

Secondly, a broad societal perspective of the economic evaluation of population screening programmes is often needed. This increases the cost of collecting data for the economic evaluation and may increase uncertainty. Screening is not just a test but a whole system of activities needed to achieve risk reduction. Depending on the circumstances, this may involve elective treatment, recovery and rehabilitation, and an increased need for health and social care which may not be in place either. The entire chain of activities may include several providers in primary, secondary, and social care. Analysts should also be aware of 'hidden' costs, that is, where the association between participation and costs in other sectors are not obvious. For example, an invitation to participate in a screening programme or a test result could make people anxious, and some may stay home from work or go to their general practitioner (GP) for advice or request for an extra health check.

Thirdly, the full costs of providing screening programmes are usually underestimated at the planning stages (Raffle and Gray 2007). For example, Ehlers et al. (2008) concluded in a review of health economic evaluations of screening for AAAs that most studies considered only short-term hospital costs at the cardiovascular department and employed a number of 'optimistic' assumptions in favour of AAA screening. Pre-assessments of cost-effectiveness of population screening programmes seldom include the costs of the quality assurance work needed including definitions of new standards, preparation of reports, inspections and external assurance schemes, coordinating bodies, and education. It is easier to assure quality of screening if the number of people involved is relatively small, and it is an exceedingly difficult

task if tens of thousands of nurses and doctors need to have an up-to-date understanding of the programme, the technology, and the standard procedures. The requirements of the IT system, the procurement of equipment, and the maintenance agreements may also be very difficult to assess from scratch especially if the people involved in the implementation and pre-evaluation of the screening programme do not possess any prior experience in organizing population screening. Consequently, the costs of national screening programmes often turn out to be much higher than anticipated, especially if new care services require implementation or re-organization as well, or service gaps are highlighted which limit the benefits of screening. This was the case in newborn hearing screening in England which though effective in identifying screen positive infants, has struggled to achieve timely enrolment in care (Raffle and Gray 2007).

Fourthly, there are often strong beliefs in the value of screening. Researchers may have strong personal interests in starting new screening programmes and a systematic review of cost-effectiveness may additionally be affected by publication bias where only positive outcomes of screening are published.

Fifthly, results of cost-effectiveness studies cannot easily be transferred from one country to another. Whereas the evidence for the clinical efficacy may be transferable between countries with similar population characteristics, this is seldom the case with cost data. This is because of differences in the availability of healthcare resources, clinical practice patterns, and relative input prices. Disease prevalence and acceptability of tests may vary as well. Consequently, while a screening programme may be cost-effective in one country, this may not apply to another.

Finally, many cost-effectiveness analyses only compare hospital-based screening interventions with 'doing nothing', but this may not be the best alternative to population screening. There may be other approaches that represent a cost-effective way of addressing the same risk, or different ways of delivering an intervention. Furthermore, improvement science has shown that a 'knowing-doing gap' in current practice may be improved significantly through better health services management. Thus, an alternative to the implementation of a new screening programme may be improved case-finding or improvements in the healthcare pathway in the present system of care. If the randomized controlled screening trial is old, which it often is, then the comparator in the trial may not represent the best present alternative to a new population screening programme. In such cases, researchers should look for other ways to estimate cost-effectiveness. If costs and effects of screening are in fact compared to an inefficient organization, the calculated incremental cost-effectiveness ratio will be biased.

Despite the difficulties in performing pre-assessments of cost-effectiveness of screening programmes, a health economic evaluation can provide important inputs to local decision-makers on the expected 'value for money' of the programme and whether it should be started. This is preferable to not making a systematic attempt to quantify costs and consequences.

Ethics of screening

Lawrence Gostin (2000) observed that 'screening is far from a neutral scientific pursuit. Rather, screening is political...fraught with complex choices and weighing values—cost, efficiency,

autonomy, and justice' (p. 201). In view of this, screening must be viewed within its social and ethical context. However, the ethical framework for screening can be considered at more than one level. The traditional biomedical ethical approach, which primarily concerns the individual, is arguably not the most relevant one. Instead a multilevel approach is necessary to ensure that introduction of a screening programme is as consistent as possible with a given society's values. This section outlines some key ethical questions that must be negotiated if a screening programme is to be introduced.

At the *health system* or *societal* level, the implementation of screening raises questions concerning resource allocation and prioritization. Funding of any screening programme involves an opportunity cost of other healthcare services forgone. The criteria used to justify screening are generally oriented towards increasing efficiency, a utilitarian value of ensuring the greatest good for the greatest number, given available resources. However, the valuation of different outcomes may present difficult problems. For example, in Down's syndrome screening, it may be feasible to estimate the cost per affected birth prevented but it is difficult, and in some societies unacceptable, to weigh this cost against the cost of treatment and care of affected individuals.

There are also questions of equity because the proposed health benefits of screening may be differentially distributed to certain groups in the population. Some men's groups argue that since screening programmes are implemented to detect women's cancers, including breast and cervical cancer screening, fairness requires that screening programmes should also be implemented to detect cancers that affect men, including cancer of the prostate, even if considerations of efficiency do not support this. More generally, screening programmes may be used more by higher socioeconomic groups than lower-income groups and minorities. Screening, thus, has the potential to increase inequalities in health while improving the overall health of the total population. Screening outcomes, and inequalities in outcomes, should be important measures for quality assurance of screening programmes.

At the level of the *screening programme*, the selection of population groups to be screened, the choice of screening procedures, the value attached to different screening outcomes and the nature of available treatment services might appear to be purely technical issues, but these processes also raise ethical questions. A screening programme may be either universal or targeted. If a targeted strategy is chosen, there is a risk of stigmatizing the target population as being particularly associated with an undesirable health outcome, such as a sexually transmitted disease. If the target population is defined on grounds of age, as is done for breast cancer screening, then this raises questions concerning the 'right to health' of women who are either younger or older than the proposed age cut-off points. While efficiency arguments may favour a more focused strategy, considerations of equity favour a more universal approach (Sassi et al. 2001).

As discussed earlier, screening tests often have low positive predictive values and this means that there may be large numbers of subjects with false positive results and a smaller number of subjects with true positive results. Major benefits from screening are shared by a few true positives and these benefits must be balanced against potential harm to many false positives. As a minimum, this indicates an ethical requirement for adequate quality assurance to

ensure the reliability and validity of testing procedures, the safety of diagnostic services, and the adequacy of information communication to screened subjects.

The selection of screening outcomes also requires careful consideration. This is especially true for screening processes that may impact on reproductive outcomes. The possibility of making a diagnosis before birth and giving parents an informed choice over reproductive outcomes appear to be positive developments. However, these processes may be viewed as related to the concept of 'eugenics' which literally means 'well-born'. It is often used to refer to movements and social policies influential during the early twentieth century and in a historical and broader sense, it can also be a study of 'improving human genetic qualities'. It is a social philosophy which advocates the improvement of human hereditary traits through various forms of intervention (Osborn 1937; Wikipedia 2013). Although introduced with good intentions, the concept of eugenics now has negative connotations that mainly date from the Nazi period from 1933 to 1945. Contemporary developments in genetics have increased the potential for genetic screening and testing.

Finally, it is ethically unjustified to initiate screening unless adequate treatment services are available to provide treatment and care for subjects identified through the screening programme. Hence those advocating for screening programmes must also advocate for investment in appropriate treatment services.

There are also ethical issues relating to the autonomy of the individual. Most screening programmes are voluntary and should be offered to individuals, enabling them to make an informed choice to participate in screening or not. In reality, as Gostin (2000) describes, voluntary population screening programmes are offered as routine interventions with limited opportunities for individuals to opt-out of participation. Family practices in the United Kingdom are performance managed against a nationally agreed target for uptake of cervical cancer screening and this target implies limited recognition of the scope for individual discretion in participation. Consequently, there has been increasing interest in the meaning, measurement, and value of 'informed choice'. Marteau and colleagues (2001) identified two components of informed choice which are incorporated into their proposed definition of informed choice as one 'that is based on relevant knowledge, consistent with the decision-maker's values and behaviourally implemented' (p. 100). According to this definition, choices are uninformed if subjects either lack good quality information or their attitudes are not reflected in their behaviour (Marteau et al. 2001).

What kind of information do individuals need to make an informed choice? The answer varies for different screening programmes. In antenatal screening programmes which may have consequences for reproductive choices and outcomes, it is particularly important that the potential implications of undergoing a screening test should be fully understood. In newborn-screening programmes, there is a move to expand the screening tests offered to include a wider range of conditions but the significance of information provided by screening varies for different conditions, making informed choice more difficult and impractical (Nijsingh 2007).

In the context of cancer screening, the potential benefit of screening may be communicated in terms of the 'number needed to screen', which is the inverse of the absolute risk reduction

(Welch 2001). Rembold (1998) estimated that the 'number needed to screen' to prevent one death from colon cancer was 1374 over 5 years and for mammography, to prevent one death from breast cancer was 2451 over 5 years for women aged 50–59 years. From the individual's perspective, these statistics are not encouraging, however, understanding the limitations and the potential for harm from screening are equally important (Welch 2001). More aggressive cancers are most likely not to be detected as they develop rapidly and so are often diagnosed by clinical services as 'interval' cancers between screening rounds. As screening tests typically have a low positive predictive value, a positive screening test may lead to more invasive procedures with potential negative consequences. Screening may identify abnormalities that might never have caused clinical disease, leading to unnecessary treatment, as exemplified by prostate cancer screening (Welch 2001).

The information required to inform an individual's choice to participate in screening is technically complex and wide-ranging. Consequently, there may be limited opportunities for truly informed choice in routine screening programmes. In democratic societies, it may be legitimate for the state to make decisions on the implementation of screening programmes through what the Nuffield Council on Bioethics (2007) terms the state's 'stewardship' role. It is through the stewardship role that states discharge their obligation to protect and fulfil their citizens' right to health. However, this should also include promoting citizens' capacity to make informed choices through better public education about screening. Helping individuals, who may have little understanding of the issues, to make decisions at difficult times in their lives should not be the sole or even main approach (Nijsingh 2007). It is usually more helpful to increase awareness of relevant screening issues before they plan families or are offered screening tests. Much more needs to be done to develop an educated public who understand screening programmes, and in particular more communication and understanding of the broader social perspectives relevant to screening rather than simply the technical issues of test performance if screening is to be successfully incorporated and accepted widely by communities.

Organization and operation of screening programmes

Challenges in implementing screening programmes

Introducing and sustaining screening programmes

The first step in implementing a screening programme should be a formal review of the evidence to evaluate whether this supports its introduction (Box 11.4.1). If this step is omitted, screening may be introduced by enthusiasts with testing diffusing into routine practice without formal evaluation. This is particularly likely to occur with tests that are not costly and have broad public support, for example, ultrasound in pregnancy. Even when there is good evidence to support such a programme, converting existing variable local practices into a standard programme across a region or country may be more difficult than introducing a new planned programme *de novo*. In general, a decision to implement a new population screening programme should be made at the national level to make sure that only the right programmes are introduced, properly implemented, and with consistent and coherent public

and professional communications. It is important to avoid having a screening programme start on its own without coordination, standardization, and quality assurance as sorting out the resultant mess may be far more expensive and challenging than setting a national programme up correctly from the beginning (Raffle and Gray 2007). Furthermore, once a programme is in routine use, it can be very difficult to adjust or stop even if there is no evidence on effectiveness and strong indications of harm (Gray 2009).

The decision to introduce a programme must be viewed in the context of a particular time and place. This is illustrated by international differences in approach. For example, screening for toxoplasmosis in pregnancy is recommended in France but not in the United Kingdom because of the different prevalence and epidemiology of the condition in these two countries. Likewise, a screening programme that is considered cost-effective in a high-income country may often be unaffordable in a middle- or low-income country.

Temporal variations in the need for screening are illustrated by the example of antenatal syphilis screening in the United Kingdom. Syphilis declined dramatically after the Second World War, following the introduction of antibiotics to treat the disease. By the 1990s, there were calls for the antenatal screening programme for syphilis to be stopped. However, a 1999 review argued against this because of recent outbreaks of the disease. On the basis of this review, the decision was made to continue screening and rates of syphilis have increased since that time, albeit mostly in men who have sex with men and the cost-effectiveness is now arguably not supported (Connor et al. 2000).

Clarifying objectives of the programme

Clarifying the aims and objectives of the screening programme represents another important step, which should involve professionals, users, and the voluntary sector. A classic example of a well-meaning approach to introducing screening that miscarried was the US Sickle Cell Act of 1970. This was intended to help identify those with sickle cell disease and provide care for them. However, the programme was introduced without adequate public education or planning. As a result, carriers identified by the programme were stigmatized, sometimes being refused jobs or losing employment due to misunderstanding of the differences between the disease and carrier states. Ultimately, the public refused to be tested because of the negative impacts of testing (Anionwu 2001). An important lesson from this experience is that the public need to be well informed, educated, and continuously engaged if the implementation of screening programmes is to achieve the potential benefit and be well accepted with sustained support.

Defining the scope of the programme

Defining the scope of a screening programme should be considered prior to more detailed planning as otherwise some aspects of required service development may be omitted, causing difficulties later. In the United Kingdom, the term 'screening programme' is defined as 'the whole system of activities needed to deliver high-quality screening. This encompasses identifying and informing those to be offered screening through to the treatment and follow-up of those found to have an abnormality, as well as support for those who develop disease despite screening' (UK National Screening Committee 2000). A key criterion for the introduction of a screening programme is that 'clinical management of the conditions and patient outcomes should be optimized

by all healthcare providers prior to participation in a screening programme' (UK National Screening Committee 2000). For example, the introduction of a newborn hearing programme requires planning and development of a service of adequate capacity and quality in tertiary specialist centres. These aspirations have seldom been achieved by the time screening is introduced.

Planning implementation

Planning and implementing the programme should cover a range of aspects such as education and training and standardization of testing procedures. These processes require project planning skills and the overall coordination and sequencing of programme implementation is important. Clinical services may be overwhelmed if a screening programme were to suddenly start which placed significantly increased demands on them. Conversely, if services are set up and referrals do not occur relatively quickly, there may be disillusionment and disinvestment. It may be optimal if services experience some increase in demand early on but without overwhelming them. Professional and public education need time to implement and should precede public awareness campaigns in order to avoid difficulties for frontline professionals. The United Kingdom experience and approach to planning and implementation are discussed in detail by Raffle and Gray (2007).

Information systems

Adequate information and information systems should not be neglected in the planning and budgeting for a screening programme. Information systems are needed to manage the process of screening, provide fail-safe systems, and monitor and assist evaluation of the outcomes of screening programme.

A characteristic of an effectively delivered screening programme is that population-orientated fail-safe systems operate independently of the individual practitioners responsible for patient care. These systems should ensure that all those eligible are offered screening, that those with inconclusive, missing, or screen-positive results are followed up and managed appropriately. Problems with these processes should be rapidly identified and addressed. In the cervical screening programme a series of fail-safe actions are identified at the level of the call-recall system, the general practice, the cytology laboratory, and the colposcopy clinic that follows up cases requiring further management (National Health Service Cancer Screening Programme 2004). Screening programmes that do not operate such systems are unsafe and risk high-level failures of process with loss of population support.

Data derived from information systems are also important for quality assurance and in monitoring programmes' success against specified objectives in terms of population outcomes. Failures of process may be less visible in the early stages of the programme but may cause problems later on. In addition, without adequate information, it may be difficult to demonstrate the benefits of the programme and hence to maintain investment.

Quality assurance/improvement in screening programmes

Importance of quality assurance

Quality assurance and performance management should be integral parts of any organized screening programme, with the overall aim of ensuring that the programme achieves the potential health benefits while minimizing associated risks and harms.

The process of quality assurance

The term 'quality assurance' refers to the process by which the quality of a screening programme, in all its key dimensions, can be evaluated and improved. Variations in quality should be identified so as to actively correct problems or implement improvements. According to Donabedian (2003), a narrow definition of quality assurance requires the collection and interpretation of information, followed by making adjustments to the system. A wider definition includes processes of system design or redesign, linked to resource allocation so as to address problems, as well as including educational and motivational activities to modify the behaviour of health professionals. Quality assurance should be cyclical: moving from assessment of performance, to action, followed by review. Quality assurance has little meaning if it operates only as a monitoring and reporting cycle, in isolation from those able to make real changes and allocate resources to address problems. A well-developed quality management system should specify when and how any task is to be undertaken and by whom (Balmer et al. 2000). A named individual should be identified as responsible for the quality of each component of the screening process, with involvement of the whole organization to plan, deliver, and evaluate quality of services (Moullin 2002). Strong user involvement in the process is recommended. Service quality is dynamic and standards should be continually reviewed and tightened so that quality is maintained and progressively increased, particularly in response to rising expectations from patients. Communication is a key aspect of maintaining quality and good partnerships between service providers are required (Moullin 2002).

Dimensions of quality

The processes of quality assurance should address several dimensions (Donabedian 2003). *Effectiveness* should be enhanced so as to optimize the benefits or health gains from screening. *Efficiency* is required to ensure that the maximal benefits are obtained from available resources. The *equity* of screening uptake and screening outcomes should be evaluated to ensure that screening is accessible to all eligible groups and benefits are fairly distributed. The *safety* of screening programmes is important to ensure that errors are avoided and harms are minimized. The *acceptability* of the screening programme to the public and service users should be ensured. Standards for any programme should encompass each relevant dimension of quality.

Measuring and monitoring quality: developing criteria and standards

To successfully monitor the quality of a programme first requires determination of what to monitor. Clarifying the agreed objectives for a programme should be the first step, using the evidence that supports the introduction of the programme as a starting point. Following this, key priorities for monitoring should be identified including structures, processes, and outcomes (UK National Screening Committee 2003).

Raffle and Gray (2007) recommend defining the objectives of a programme to encapsulate what a 'good' programme should look like. Box 11.4.2 gives an example from the sickle cell and thalassaemia screening programme in England. A similar approach has been used in the United Kingdom for other programmes including

Box 11.4.2 Example of screening programme aims and objectives—NHS newborn sickle cell screening programme

Programme aims

- ◆ To achieve the lowest possible childhood death rate and to minimize childhood morbidity from sickle cell disorders.

Overall outcome to be achieved at national level

- ◆ Mortality rate in children with sickle cell disorders under 5 years of less than 4 per 1000 person years of life (two deaths per 100 affected infants) by 2010.
- ◆ To identify with specific sensitivity babies born with conditions where early intervention is likely to be beneficial.

Programme objectives

- ◆ To offer screening for sickle cell diseases to all infants.
- ◆ To process tests and report results in a timely manner.
- ◆ To identify and arrange timely follow-up of infants identified as needing further investigation.
- ◆ To ensure effective and acceptable follow-up, care, and support for affected infants and their carers.
- ◆ To ensure treatment is offered and parental education is started in a timely manner.
- ◆ To minimize the adverse effects of screening—including failure to follow up screen-positive infants, inaccurate or inadequate information, unnecessary investigation and follow-up, inappropriate disclosure of information and failure to communicate results to parents (normal and carrier).
- ◆ To ensure that responsibility, accountability, and performance management for all aspects of the programme are clear and that these link together from local to national level and between the newborn and antenatal programme.

Reproduced from the National Health Service Sickle Cell and Thalassaemia Screening Programme, *Standards for the Linked Antenatal and Newborn Screening Programmes*, Second Edition, NHS Sickle Cell and Thalassaemia Screening Programme, London, UK, © Crown Copyright 2011, licence under the Open Government Licence v.2.0, available from <http://sct.screening.nhs.uk/standardsandguidelines>.

the breast screening and diabetic retinopathy programmes. Once objectives are defined, ways of measuring their attainment should be identified, with specific criteria and standards developed for each. A criterion is defined 'as an attribute of structure, process, or outcome that is used to draw an inference about quality' (Donabedian 2003, p. 60). A standard is defined as 'a specified quantitative measure of magnitude or frequency that specified what is good or less so' (Donabedian 2003, p. 60). Criteria, therefore, cover the key dimensions of quality to be assured, while standards specify exactly what is to be expected for each.

Ideally, a baseline assessment of performance should precede and inform the setting of the screening programme standards. Standards may include both minimum acceptable standards to be achieved by all, and achievable standards that might be reached by the top quartile of programmes. Achievable or developmental standards target attainment in an environment of increasing expectations. The process of setting standards is iterative and continuous, requiring regular review, particularly in the early years of a programme. Once set, it is necessary to identify the interventions required to meet the standards, to monitor service delivery against standards, and for continuous improvement of services. Standards should also be based on an understanding of patients' requirements and expectations. Moullin (2002) recommends that standards should be realistic and achievable within available resources; service users should contribute to the development process.

The measurement of outcomes of screening programmes can be very challenging but is essential. Outcomes of a programme are generally assessed at national- or state-wide level, in contrast to the quality assurance process which is more useful for assessing the operation of a programme at a local or unit level. Table 11.4.3 gives an example of the outcome standards set for the newborn screening programme for sickle cell disease in England (National Health Service Sickle Cell and Thalassaemia Screening Programme 2011).

Different types of programmes and the different challenges in their organization

The challenges of screening are typically presented in relation to screening for cancer, although screening also covers infections, genetic conditions, and vascular conditions.

Infections

Examples include pre-conception syphilis screening as recommended in the United States; hepatitis B, rubella susceptibility,

and HIV screening in pregnancy in the United Kingdom; and toxoplasmosis screening in pregnancy in France. The purpose of screening should be clarified as different actions and subsequent monitoring may be required. Screening for infection may identify susceptibility, as in the case of rubella screening that may indicate a need for immunization. Screening may identify past infection and sero-conversion, as in the case of hepatitis B and HIV, with potential benefits of intervention for the infant (hepatitis B) or both mother and infant (HIV) (Department of Health 1998). In pregnancy, there may be benefits either for the mother and/or the baby. Most of the benefits to the infant will be gained if infections, such as syphilis, are identified before pregnancy.

A specific problem of infection screening, such as HIV in pregnancy, is that a non-immune individual can subsequently become infected after a negative screening test. The same applies, for example, to screening of migrants for TB who are at high risk of reinfection due to environmental conditions. Screening may also fail to detect very recently infected individuals if the test is for sero-conversion. Screening may, if inappropriately applied as in the case of a meningitis outbreak, identify asymptomatic carriers of a particular organism.

Genetic screening as distinct from genetic testing

Developments in genetics have opened up many new possibilities for the diagnosis of a variety of diseases, but the same principles apply as for other forms of screening despite the historical tendency to 'genetic exceptionalism'. If genetic tests are offered, either there must be an effective intervention available for individuals found to be affected, or the information provided by the result must help the individual or other family members to make better decisions than if the information was not available. This section specifically considers the application of genetic tests to populations, that is, screening (for genetic testing see Chapter 2.5).

Genetic tests may be used in a variety of settings for differing purposes, including diagnostic testing, to confirm or exclude a genetic disorder in an asymptomatic individual, and predictive testing in asymptomatic individuals who have a family history. In most situations, genetic tests are applied to individuals known to be at high risk and hence, these are not defined as 'screening'. Examples of genetic screening at different stages of the life course include firstly newborn screening to identify *affected individuals* and start treatment as early as possible, for example, cystic fibrosis and sickle cell disease; and secondly, *carrier identification* to assist reproductive choice before birth of an affected individual and to identify couples at risk. Worldwide, carrier tests are

Table 11.4.3 Outcome measures for a newborn sickle cell screening programme in England

Outcome	Criteria	Minimum standard	Achievable standard
Best possible survival for affected infants detected by the programme	Mortality rates expressed in person years	Mortality rate in children under 5 of less than four per 1000 person-years of life (two deaths per 100 affected children)	Mortality rate in children under 5 of less than two per 1000 person years of life (one death per 100 affected children)
Accurate detection of all infants born with major clinically significant abnormalities	Sensitivity of the screening programme	99% for HbSS, 98% for HbSC, 95% for other variants	99.5% for HbSS, 99% for HbSC, 97% for other variants

Reproduced from the National Health Service Sickle Cell and Thalassaemia Screening Programme, *Standards for the Linked Antenatal and Newborn Screening Programmes*, Second Edition, NHS Sickle Cell and Thalassaemia Screening Programme, London, UK, © Crown Copyright 2011, licence under the Open Government Licence v2.0, available from <http://sct.screening.nhs.uk/standardsandguidelines>.

usually offered preconception but they can be offered at any time up to early pregnancy and in high-risk groups to enable individuals to make informed choices. Well-known examples include carrier screening for thalassaemia (Bozkurt 2007; Cousens et al. 2010) or Tay–Sachs disease (Amato et al. 2009). For autosomal recessive conditions, if both partners are carriers, there is a one-in-four risk in each pregnancy of an affected infant and testing pre-conception offers a wider range of choices than testing in pregnancy.

Other ongoing developments in screening and testing which are likely to become more debated include non-invasive genetic tests of maternal blood (cell-free fetal DNA testing) (American College of Obstetricians and Gynecologists 2012). In some common conditions, preventive genetic testing may contribute to the identification of individuals at high risk; for example, *BRCA1* and *BRCA2* gene mutations, which can identify women at particular risk for developing breast cancer. Testing for *BRCA1* and *BRCA2* does not meet the criteria for a screening programme in populations at low risk of the condition.

Challenges of genetic screening

The Human Genome Project has raised public expectations of genetic screening but it is essential to appreciate the associated problems. The human genome has several million single nucleotide polymorphisms, and thus, the ‘number of possible genetic associations is limited only by the rate at which laboratories are able to type these polymorphisms’ (Colhoun et al. 2003). These difficulties are often neglected as is the fact that *associations* of a gene with a condition should be subjected to the same rigorous assessment as the findings of an environmental risk factor associated with a disease.

As with all screening tests, genetic screening may have psychological consequences, thus adequate counselling services must be provided. For common conditions, genetic screening is unlikely to be of great use in view of the complex interaction between environmental, behavioural, biological, and genetic factors. Its use is likely to be greatest in screening populations for a few clearly defined single-gene conditions. For example, its application has been followed by a reduction of rates of thalassaemia in a high-risk population in Iran, where treatment costs for those affected are considered unaffordable to the society and individual families who hence wish to have the option of prenatal diagnosis and termination (Samavat and Modell 2004).

An issue arising with newborn screening programmes for both cystic fibrosis and sickle cell disease is that the methods currently used by programmes aiming to detect disease cases also detect the carrier state. In England and the United States, there has been a debate as to the merits of revealing carrier status to parents of infants at a stage where the child cannot make such a decision. In both, the view that has prevailed is that if the condition is identified as part of screening ‘carriers should be reported to parents and follow-up counselling is offered to ensure understanding of the difference between carrier state and disease and also the genetic significance of the carrier state’ (Human Genetics Commission 2006, 2011; Lin and Barton 2007). The UK Human Genetics Commission (2006) emphasizes that such decisions must at their core reflect societal views and not the views of technical experts. This is particularly relevant if preconception screening is not available especially now that preimplantation genetic

diagnosis is more routinely available (Gøtzsche 2012). A second common problem, particularly relevant to newborn screening and carrier testing to identify couples at risk, is the potential to identify non-paternity. This underscores the importance of public education and awareness about such programmes starting with secondary school-aged children.

Governance of screening programmes

Population screening programmes should generally adhere to the principles of good governance described in Chapter 6.8, such as the rule of law, transparency, responsiveness, consensus orientation, equity and inclusiveness, effectiveness and efficacy, and accountability. There are, however, a number of inherent dilemmas and conflicts of interests in the governance of population screening that necessitate separation of responsibilities and authority between the national level, the regional/local level, and third-party inspection roles.

Public expectations of screening (including the media) are usually very high and there is a poor understanding that screening cannot detect all cases of illness and may cause harm. Examples of lawsuits against responsible physicians and ‘scandals’ reported in the media threaten to reduce transparency and accountability because health workers also have a need to protect themselves against wrongful accusations. Handling of the media and communication of evidence about what a screening programme should and should not be expected to deliver are better performed at the national than the local level. Inspections of the quality are more likely to establish trust if they are done by a third party than by those doing the screening. In cases where the public and media threaten to drive increases in sensitivity to avoid missed cases, external controls may be a more efficient way to guard against overdiagnosis and overtreatment.

Conflicts of interest may also arise in decisions to start, expand, contract, or stop a screening programme. Local physicians may have personal interests in starting and expanding programmes for research, financial, or other private reasons. Local agencies may be seeking to maximize their budgets or enlarge their staffing, and these conflict with the principles of effectiveness and efficacy. Companies with a market interest and other interest groups such as patient organizations cannot be expected to provide a truly balanced view and may threaten the consensus-oriented principle of doing the most beneficial thing with scarce resources. Even scientific societies may be biased towards screening because they also represent local interests in the matter. For these reasons, a decision to start screening should be taken at a national level and definition of standards, clinical guidelines, and quality assurance should not solely be a local matter.

Evaluating, restricting, and stopping existing programmes

Evaluation of ongoing screening programmes should be part of their oversight. It should be performed regularly using the same stringent framework to ensure that the programme is performing and delivering the outcomes expected of it, and that it still represents the best use of scarce healthcare resources. This requires a commitment to the collation of data and external independent review.

National health authorities may over time wish to restrict or stop existing screening programmes for a number of different reasons: some screening programmes may have started haphazardly without a national decision based on solid evidence. In a for-profit health system there is a market for all kinds of tests even without proven effect. Private insurance companies selling whole-body computed tomography scans or routine periodic health examinations are examples. In public healthcare systems, the use of inexpensive and easily accessible tests may also turn into de facto screening programmes driven by public demand, commercial, or private interests. If, later on, new research evidence show a lack of benefits and/or serious adverse events it will be necessary to restrict or stop the screening activities.

The balance between the good and harm may also change over time. Even if the introduction of a screening programme was initially based on a national decision supported by solid evidence, and even if the programme was carefully designed and piloted and nationally coordinated the programme may eventually grow beyond its optimal size. If programme activities are over-resourced, screening may be performed too often or in too many subgroups. As more resources are invested in a screening programme the law of diminishing returns prevails. The extra benefits obtained from screening decrease disproportionately with increased harm, and after a certain point of time, the net health gain starts to decline. Thus, overinvestments need to be withdrawn and the scope of the programme reduced to its optimal size (Donabedian 2003; Gray 2009).

Other factors such as changes in epidemiology or costs, technological developments, new research findings, or knowledge of alternative ways of preventing disease (or reducing risks) may change the opportunity costs of the programme. Funding shortages may also call for restricting or stopping existing activities. Once a screening programme is implemented, however, it may be extremely difficult to stop or restrict the scope even if it bears no provable health benefits and does harm (Raffle and Gray 2007). For example, in Denmark, it took 20 years after TB was eradicated before TB stations were closed down and before a large company like the Carlsberg breweries stopped mandatory chest X-rays for all newly employed personnel. In all those years, the screening activities were more harmful than beneficial as X-rays carry a small risk of inducing cancer (Gøtzsche 2012).

Experience shows that it may take years to stop harmful screening practices (Raffle and Gray 2007). Many politicians support screening because they feel the need for 'doing something', and screening may intuitively seem worthwhile to most people. Screening programmes can be strongly supported by advocacy groups, interest groups, or commercial interests. Raffle and Gray (2007) describe what they call the popularity paradox that the greater the harm through overdiagnosis and overtreatment from screening, the more people there are who believe they owe their health, or even their life, to the programme. Reducing or stopping screening activities can only be done through governmental intervention and only if there is an organizational and political governance structure that enables and facilitates such decisions. For example, the Japanese child neuroblastoma screening programme started in 1985. After an international panel in 1990 concluded that screening did not reduce mortality but resulted in harm, a national committee under the Ministry of Health, Labour and Welfare reviewed the policy and stopped the programme in 2004.

The Japanese media was generally supportive of the Government's recommendation. There was widespread public awareness about the pitfalls of cancer screening. There was little demand among parents (due to limited knowledge of neuroblastoma) and, perhaps most importantly, no advocacy groups in favour of screening (Raffle and Gray 2007).

Formal evaluations of existing screening programmes are a key tool for stopping or restricting screening programmes and for continuous improvements in their operations. A clear distinction should be made, however, between regular evaluations of the operation of a programme and independent (external) critical and research-based evaluation of a screening programme suspected of producing more harm than good. The first is part of an ongoing process of review and quality improvement while the latter serves as an input to deciding whether or not to restrict or stop an activity. Both types of evaluations are costly but necessary. The costs of not doing both types of evaluations are the human and financial costs of potential harmful and ineffective screening.

Formal evaluations of the operation of ongoing screening programmes should be performed regularly. A stringent framework should be applied to ensure that the programme is performing and delivering the outcomes expected cost-effectively. The same criteria that should be met before screening is initiated should also be met when the programme is up and running. The programme should adopt the principles of good governance and performance according to the highest possible quality standards. It is also important to ensure that relevant data on the epidemiology, test performance, and outcomes are collected from the outset. Evaluation of ongoing programmes should be seen as an important supplement to short-term performance reporting of process measures as they may provide important information that lead to changes in the policies or practices, or uncover problems that require more research. This type of evaluation, however, can probably never lead to programmes being closed down.

There should be an independent national body to commission and/or grant new research to secure formal independent external evaluation of existing programmes whenever needed. Depending on the circumstances this may be done on a regular basis, for example, every fifth year or on an ad hoc basis. Such independent evaluations should be performed with the explicit aim to investigate whether or not the programme should be restricted, expanded, or stopped. Research-based evaluations are able to provide good input to a decision whether or not to stop or restrict a programme only if researchers are truly independent, unbiased, and professional. For example, Gøtzsche (2012) describes the need for independent reviews of national breast screening programmes (especially in woman aged over 40) and explains how, in an environment dominated by powerful people in favour of screening, it may be almost impossible to establish truly independent evaluation committees. Furthermore, where professionals are convinced of the benefits from screening, this may hinder necessary research. Quality assurance and regular formal evaluations will not automatically ensure that harmful screening programmes will be stopped. While continuous quality assurance can reveal that certain policies or activities within the programme should be changed, these are performed by the professionals working in the programme and who are all, presumably, convinced of the net benefits of screening. Stopping the programme will probably never be considered a real option.

Healthcare systems should therefore have the capacity for independent critical evaluations performed by unbiased research units. Such evaluations can be done anonymously to avoid legal accusations and other reprisals from those who strongly favour screening. However, it is important for independent researchers to be engaged directly with policymakers (and advocacy coalitions) to influence agenda setting and prepare a way for changing current practices (Gibson 2003; Buse et al. 2009).

An example where evaluation of an ongoing screening programme is crucial is cervical cancer screening, where new HPV immunization programmes are predicted to reduce the number of screen-detected cases. If the immunization programme is effective, it will gradually reduce the need for screening and, at some point, decisions will need to be made about scaling down or perhaps even stopping population screening.

Screening at different stages of life

This section provides a brief summary of debates concerning screening at different stages of life.

Antenatal and newborn screening

One of the most comprehensive reviews on appropriate procedures in the antenatal and neonatal period was published by Wald and Leck (2000). Screening during this period has been shown to be of particular importance and been used longest. Even so, many questions remain. Recommendations in the United Kingdom for antenatal screening include Down's and fetal anomalies, thalassaemia and sickle cell disease, infectious disease (HIV, hepatitis B, syphilis). Conditions not recommended for antenatal screening include: group B *Streptococcus*, *Cytomegalovirus*, *Chlamydia*, hepatitis B, HTLV1 toxoplasmosis, domestic violence, and pre-eclampsia.

Newborn screening

Screening of newborn infants consists of routine biochemical tests on an infant's blood spot and physical examination including testing for hearing impairment. In the United Kingdom, current recommendations are for testing for phenylketonuria, congenital hypothyroidism, cystic fibrosis, sickle cell disease, and medium chain acyl-CoA dehydrogenase deficiency with a proposal to introduce three more conditions. Physical examination is usually performed in the first year of life, seeking signs of congenital heart disease, congenital cataract, cryptorchidism, congenital dislocation or developmental dysplasia of the hip, as well as other congenital malformations. The latter has been controversial, but evidence of the effectiveness of ultrasound screening is now accumulating. A national screening programme for hearing impairment has been implemented in the United Kingdom.

Screening in childhood

Screening in childhood is important, both to follow up findings from the neonatal period and to identify remediable defects or problems. A large number of bodies recommend a variety of procedures at different stages. Screening for hearing, visual impairment, and congenital hip displacement is straightforward, but there is also a need to identify children from disadvantaged households who are at particular risk of developing both physical and behavioural impairments which are often neglected.

Screening in adolescence

The major need at this stage is to build on the findings of the schoolchild examinations and provide confidential accessible health services to aid the adolescent to confront and deal with such problems as fertility and sex, drugs, and alcohol use. All opportunities should be taken to educate the adolescent on healthy living, personal safety, nutrition, exercise, and so on. Only opportunistic testing (rather than screening) is recommended for *Chlamydia trachomatis*, a common, curable sexually transmitted infection which is often asymptomatic but can lead to life-threatening ectopic pregnancy, pelvic inflammatory disease, and infertility. Some areas such as Montreal, Australia, and Rome, have introduced school education followed by the offer of carrier testing for relatively common recessively inherited conditions. Due to the burden of disease, many countries also offer various forms of pre-marital testing, most notably in Cyprus for thalassaemia major (Bozkurt 2007; Cousens et al. 2010).

Screening in adults

Screening in adults is big business. Media interest in health is insatiable and politicians have capitalized on public expectations and beliefs that 'prevention is better than cure'. It is therefore essential to critically consider the benefits and disadvantages of screening procedures.

Cancer

As the second largest cause of mortality in high-income countries, cancer is potentially an important area of health benefit. Specific problems for cancer screening are 'length-time' and 'lead-time' biases. Length-time bias refers to the fact that screening is most effective at detecting slow developing cancers which are less likely to be the cause of an individual's death but by detection can cause considerable anxiety. More aggressive tumours are likely to develop rapidly in the intervals between screening rounds. Lead-time bias refers to the problem for evaluation of programmes that detect cancers earlier than would have been the case with symptomatic screening and may thus appear to lengthen the time from diagnosis to survival when there is no true change in natural course or treatments which may even shorten life expectancy.

Breast cancer

The major trials of breast cancer screening have been done in the United States (Shapiro et al. 1982) and Sweden (Taban et al. 1985, 1989). Other trials were done in the United Kingdom, which before introducing a national scheme of breast cancer screening, had a major public enquiry (Forrest 1987). Screening for breast cancer is a highly emotive subject which has been the subject of very critical analysis (Gøtzsche et al. 2012). Under research conditions, as in the two original studies, there is a reduction in breast cancer mortality following mammographic screening. The reduction in total mortality in the test group is not so marked and the benefits in practice are smaller. There are arguments about which age range of women should be included in the scheme, the methods of mammography, the interval between repeat screening, and the interpretation of mammograms. There is no doubt that for the scheme to be effective, there needs to be good organization, careful quality control of both mammography and the subsequent breast biopsy, as well as good specialized treatment services including surgery, radiotherapy, and chemotherapy. The scheme, if properly

executed, is costly, and critics suggest that the resources could be better used on clinical breast cancer treatment services. The major problems with the services are poor information to participants, increased anxiety in those screened, particularly the false positives, side effects from the biopsy, and the risks of radiation exposure. The most recent UK review (The Independent UK Panel of Breast Cancer Screening 2012) continues to recommend screening 50–70-year-old women every 3 years. In view of the popularity of breast cancer screening, it would be a daring policymaker who would suggest that the scheme should cease.

Cervical cancer

A programme of screening was first proposed in the mid 1960s. The original scheme was wasteful, including any woman attending any gynaecological service or family planning. In the United Kingdom, since 1998, the service has been re-launched on the basis of a call–recall system based on the GP patient register. Women are first invited at the age of 25 years and then recalled every 3 years until age 50 when the interval is increased to 5 years. About 80 per cent of the eligible women are screened, comparable to breast cancer screening coverage. Although mortality from cervical cancer has fallen considerably, it required an enormous effort. Raffle (2004), in an analysis of screening records of 348,419 women in Bristol, calculated that 1000 women need to be screened for 35 years to prevent one death, over 80 per cent of women with high-grade cervical intra-epithelial neoplasia will not develop invasive cancer but all will need to be treated, and for each death that is prevented, over 150 women have an abnormal result, over 80 women are referred for investigation, and over 50 women receive treatment.

The original test method of cytological examination has been superseded by liquid-based cytological examination and now by HPV culture which allows automation. In future, cervical cancer prevention through screening may be superseded by the HPV vaccination which is now introduced for girls aged 13 years in the United Kingdom and for boys and girls in Australia.

Colorectal cancer

A number of studies have shown that early detection by screening can reduce mortality (Hardcastle et al. 1996; Kronborg et al. 1996). As a result, screening for individuals aged over 50 years has now been introduced in the United Kingdom. Individuals are mailed a filter paper to be returned to the centre for faecal occult blood testing (FOBT). If the screening test is positive, then a colonoscopy and/or double-contrast barium enema is performed. Some advocate flexible sigmoidoscopy as an alternative before these procedures. It is suggested that the screening tests are done at 5-yearly intervals. Some authorities advocate screening by colonoscopy.

Prostate cancer

Although a biochemical screening test—prostate specific antigen (PSA)—and digital rectal examination and transrectal ultrasound are available, confirmation by biopsy is essential.

Prostate cancer is one of the commonest cancers in men, particularly the elderly. It has therefore become a ‘cause celebre’ in screening arguments advocated strongly by many groups, particularly prostate charities, male advocacy groups, and commerce. It has been the subject of intense argument and review. Although it is common, many more men die with the cancer than of it (Martin 2007). Many studies have not shown any evidence that mortality is

reduced or postponed if screening is undertaken in asymptomatic individuals. With present knowledge, there is no case for screening well individuals but those with prostate symptoms of frequency nocturia, inadequate voiding, etc. should be investigated and it should be noted that this is an area of very active research.

Type 2 diabetes and diabetic retinopathy

Type 2 diabetes is common but there are divided views about the usefulness of screening for it. Wareham and Griffin (2001) do not advocate universal screening. The UK National Screening Committee also does not consider population screening worthwhile. Diabetic eye disease is the most common cause of preventable visual loss in the UK working population. Different methods of screening for diabetic retinopathy are available and have been evaluated (Squirrel and Talbot 2003). These use retinal photography and screening by optometrists. They are certainly worthwhile, but must be subject to stringent quality control and audit. They are quite difficult to establish satisfactorily although a successful programme has been implemented in the United Kingdom, but there remain challenges reaching those most likely to benefit from screening (Forster et al. 2013).

Cardiovascular disease

There is an ongoing debate regarding the merits of screening for cardiovascular disease (this includes coronary heart, disease, stroke, and AAA). The main risk factors for these conditions (smoking, raised cholesterol, lack of exercise, overweight, and hypertension) are very common in Western populations. Approaches to risk reduction in the whole population have been advocated instead of screening as being the most cost-effective. In the United Kingdom, a whole-population systematic approach to case finding has been introduced. This aims to help prevent heart disease, stroke, diabetes, kidney disease, and certain types of dementia by offering a check to assess the individual’s risk of heart disease, stroke, kidney disease, and diabetes and to give support and advice to help them reduce or manage that risk (NHS Health Check 2014). Evidence of the benefits of AAA screening is demonstrated for areas with higher prevalence of the condition (Elhers et al. 2008).

Mental illness

Depression is the third commonest reason for consultation in general practice in England. A variety of questionnaires have been proposed for screening for this condition but none have met the criteria for an effective instrument. Arrol et al. (2003) in New Zealand found two questions—‘During the past month, have you often been bothered by feeling down, depressed or hopeless?’ and ‘During the past month, have you often been bothered by little interest or pleasure in doing things?’—detected most cases of depression. There is a case for opportunistic screening for depression using such a simple questionnaire in general practice. There do not appear to be appropriate indications for screening for other mental conditions or personality disorders, alcohol misuse, or domestic violence.

Screening in the elderly

This is an important issue in view of the increasing proportion of the elderly in many societies. Scientific evidence of the benefits of screening in this age group is sparse.

In a randomized controlled 3-year trial in Denmark, Hendricksen et al. (1984, 1989) showed reduced mortality resulting from a programme of 3-monthly home visits that improved the provision of home help, equipment, and modifications to the home. The costs incurred were offset by savings, which were twice as great, from reductions in hospital nursing home care.

Since elderly persons have more contact with primary care services than any other age group, these contacts should be used for opportunistic case finding of common conditions such as hypertension, hearing loss, and visual impairment, as well as symptomatic conditions like bacteriuria, incontinence, and foot problems. Behavioural concerns such as inappropriate medication, lack of physical exercise, depression, dementia, alcohol problems, and social isolation should also be considered. Home visits to those aged over 75 years may not only identify inappropriate housing, hazards in the home which may cause falls, but also social isolation, undernutrition, and elder abuse. Thus, screening in this age group is concerned with case finding and improving quality of life.

Conclusion

The concept of screening for disease offers the possibility of bringing beneficial health interventions to apparently healthy subjects, free from known disease. This chapter has discussed some of the difficulties associated with this approach. These problems must be analysed from several different disciplinary perspectives. The epidemiological approach is required to analyse problems of screening-test performance, as well as questions of the effectiveness of intervention through screening. Applying screening techniques raises important ethical questions concerning the relationships between individuals, screening programmes, and the wider society. These reflect uncertainty and disagreement as to how the benefits and harms from intervening through screening should be valued and distributed. Developing a screening programme represents a complex technical challenge, and sound planning and project management strategies should be employed for implementation. Ongoing screening programmes should be continuously improved through application of quality assurance and the implementation of systems to minimize errors and harm. They should also be evaluated from time to time to ensure that the benefits expected in terms of effectiveness and cost-effectiveness are achieved and this requires ongoing systems of data collection and evaluation. Application of these principles to different screening programmes in the main areas of infections, genetic conditions, vascular disease, and cancer, and at different stages of life, requires detailed and specialized knowledge.

Environmental health practice

Yasmin E.R. von Schirnding

Introduction to environmental health practice

Concept and scope of environmental health

In considering the practice of environmental health, it is necessary firstly to have an understanding of the concept of environmental health, which can be defined in various ways. In its broadest context, environmental health is concerned with the health effects associated with the environment. This includes both the physical (natural and man-made or ‘built’) as well as the social environment. It is less concerned with the health of the environment per se as it is with its impacts on human health. In this respect, environmental health is an integral part of the discipline of public health, with strong links to the environmental sciences.

The World Health Organization (WHO) has defined environmental health in various ways to include ‘Those aspects of human health and disease that are determined by factors in the environment. It also refers to the theory and practice of assessing and controlling factors in the environment that can potentially affect health’ (WHO 1989). While *health* has been defined by the WHO as ‘A state of complete physical, mental and social well-being and not merely the absence of disease or infirmity’ (WHO 1946), environmental health has tended to focus mainly on the physical environment, with less emphasis on the social environment and on social and mental well-being. Nevertheless, both the physical as well as the social aspects of the environment are important aspects of the realm of environmental health.

An updated definition of environmental health by the WHO gives added emphasis to this social component and describes environmental health as comprising ‘those aspects of human health, including quality of life, that are determined by physical, chemical, biological, social and psychosocial factors in the environment. It also refers to the theory and practice of assessing, correcting, controlling, and preventing those factors in the environment that can potentially affect adversely the health of present and future generations’ (WHO 2004).

Virtually any aspect of the environment can affect human health—either positively or negatively. Typical environmental health concerns addressed by environmental health practitioners include ambient and indoor air quality, food safety, water quality, sanitation, waste management, housing quality, noise pollution, electromagnetic radiation, occupational and industrial hygiene, vector control, and toxic chemical exposures.

In recent years, increasing attention has been given to the health effects associated with natural ecosystems and to global (climate) change, addressing health issues in the context of complex (eco) systems analysis (McMichael et al. 2006; Patz et al. 2008; McMichael 2013). With growing appreciation of the links between ecology and health, the integrity of natural ecosystems, and the transdisciplinary and intersectoral nature of environmental health, there have been calls for new approaches to dealing with environmental health hazards (Soskolne et al. 2007). With the global spotlight on sustainable development, practitioners have begun to look at environmental health risks more holistically from the viewpoint of various economic sectors like housing, transport, or energy, and settings or systems like the city at large.

In this respect, it is interesting to note how the discipline of environmental health has evolved, from its roots in the sanitation movement of the 1800s in the United Kingdom (Hamlin 1998) with a fairly narrow focus on sanitation, environmental hygiene, inspection, and control, to an increasingly broader approach addressing health and environment concerns in the context of sustainable development (von Schirnding 2002a) and with more focus on ecosystems and ecology in general (Rapport et al. 2009).

It was back in 1848, with the passage of the Public Health Act in the United Kingdom (Calman 1998), that provision was made for the appointment of Inspectors of Nuisances—the predecessors of today’s environmental health officers. This resulted from an enquiry by Edwin Chadwick, a Poor Law Commissioner, who, in 1842, published a major report on sanitary conditions in England (Chadwick 1842). Chadwick’s investigation into the causes of poverty concluded that people often became poor as a result of ill health from an adverse environment. That situation prevails today.

A high prevalence of ill health and disease in a population make poverty eradication and economic development elusive goals. People who are poor are more likely to get sick—however, people who are sick are more likely to become poor. Poverty eradication, economic development, and a healthy environment are inextricably linked and are fundamental to ensuring human health. A responsive health system, a healthy environment, and an intact life support system are vital to sustaining the health of the population. In the following subsections, we look briefly at some of the major trends in health, environment, and development in recent years, before highlighting environmental health issues and the burden of environmentally related disease.

Global trends

Of overriding significance is the fact that on a global scale there has been unprecedented wealth creation and economic development in the past decades, coupled with intensified global efforts targeting major causes of death and disease throughout the world. This has been accelerated in part due to initiatives such as the Millennium Development Goals (MDGs) process which set in motion an ambitious programme of goals and targets to eradicate poverty by the year 2015 (United Nations (UN) 2000).

Life expectancies for men and women are increasing. For example, from 1970 to 2010, life expectancy at birth for males increased from 56.4 years to 67.5 years, and for females from 61.2 years to 73.3 years (Wang et al. 2013). A greater proportion of total deaths now occur among people over the age of 70 years, compared with 20 years ago. There have been significant declines in infectious disease mortality, and burdens of HIV and malaria are falling. Far fewer children under the age of 5 years are dying (Wang et al. 2013) with deaths in this age group having declined by almost 60 per cent since 1970.

Nevertheless, despite huge progress in human development over the past decades, today, one out of five people live on US\$1.25 per day or less, and big gaps in progress remain in some regions of the world. The most afflicted continent is Africa. Moreover, the distribution of income at the country level has worsened in much of the world, despite narrowing in gaps in health and education (United Nations Development Programme (UNDP) 2011).

Human population growth continues apace, increasing by 75–80 million people a year (Sachs 2012) and projected to reach a total of 9 billion by the middle of the twenty-first century and 10 billion by the end of this century. It is estimated that 3.4 billion people (around half the world's population) currently live in urban areas, and by 2050 this number may rise to 6.3 billion. Sixty per cent of the global population will be living in cities by 2030. Urban growth will be greatest in Africa and Asia, followed by Latin America and Oceania. While currently it is estimated that about 1 billion people live in slum-like conditions, by 2030 this number could double (Satterthwaite 2007).

With rapid economic development and urbanization in developing countries, air and water pollution levels have been increasing, as has the generation of municipal and hazardous waste. In the last 30 years, however, in many industrialized nations stronger environmental laws have resulted in cleaner and safer drinking and recreational water as well as in improved air quality. On a global basis nevertheless, the trend for pollution of air and drinking water supplies is upward (McMichael et al. 2006; Goldman and Torres 2009). Growth in incomes has been associated with deterioration in key environmental indicators such as carbon dioxide emissions, soil and water quality, and forest cover (UNDP 2011).

Environmental health issues

Environmental health practitioners face a growing diversity of environmental hazards to deal with, in many different settings, in developed and developing countries alike. Often it is difficult to distinguish the traditional risks associated with poverty from new and emerging ('modern') ones associated with urbanization and industrialization, agriculture, and land-use practices. Developing countries frequently must deal simultaneously with the impact

on health of both. For example, pesticides and faeces may contaminate the same water supplies, and air pollution may stem simultaneously from burning dirty household fuels and the use of industrial fossil fuels (World Resources Institute et al. 1998).

Problems may have to be dealt with simultaneously at the global, national, and local levels. For example while water supply and sanitation, waste disposal, or toxic chemicals are often of special relevance at the local or micro level, other problems are more important at the regional or global level (global climate change, or long-range transport of air pollution). Health impacts associated with global change and disturbances to natural ecosystems (disruption of bio-geophysical systems such as the climate system and associated rising temperatures, declining rainfall, extreme weather events, degradation of land and water, depletion of resources, and other effects) (McMichael 2013) have to be dealt with at all levels, and may impact severely on poor countries and on the poor in general. While poor countries have contributed least to global climate change they have experienced the greatest loss in rainfall and the greatest increase in its variability, with implications for agricultural productivity and livelihoods (UNDP 2011).

While problems may differ in urban and rural environments, increasingly the divide between urban and rural is becoming blurred. Cities have provided numerous positive benefits associated with increased job opportunities and provision of essential services and facilities, but environment and health problems may nevertheless be profound, especially in cities that are not economically homogeneous. In informal settlement areas in particular, infectious diseases associated with inadequate water and sanitation, and dirty household fuels may be prevalent. Rich and poor people live in very different epidemiological worlds, even within the same city, and this situation occurs in both high-income as well as low-income countries (WHO and UN-Habitat 2010). Infant mortality rates are often higher among poor segments of urban populations in developed countries.

Lead poisoning illustrates very well the unequal burden of risk borne by poor inner-city children who are not only more exposed to sources of lead in and around the home environment (from flaking lead-based paint, for example, or contaminated air and dust), but are also more vulnerable to the toxic effects of lead, being often nutritionally deprived and having inadequate access to healthcare facilities. This is true even of children living in such countries as the United States and parts of Europe (Tong et al. 2000). Within inner-city areas, studies from South Africa have shown substantial socioeconomic differentials in blood lead burden among inner-city children (von Schirnding et al. 1991).

Poorer countries also have higher levels of household deprivation as evidenced by such factors as indoor air pollution, and inadequate access to clean water and sanitation. The environmental burdens of poverty fall directly on poor populations. As income levels rise, however, and with increased affluence and associated lifestyles and consumption patterns, these burdens tend to lessen, concomitant with environmental burdens which are more diffuse, indirect, and delayed, and affect a more temporally and spatially displaced public (UNDP 2011). Risks associated with community urban air pollution are an example.

With further economic development, these more localized burdens tend eventually to lessen too (or be displaced elsewhere), while environmental risks associated with global effects—for

example, greenhouse gas emissions—tend to rise with high levels of materials and energy consumption and waste generation (UNDP 2011). The most disadvantaged people carry a double (or triple) burden of deprivation—they are more vulnerable to the global effects of environmental degradation, have often to cope with new and emerging risks associated with rapid industrialization and urbanization, but also have to deal with threats to their immediate environment like indoor air pollution, dirty water, and poor sanitation.

Burden of disease

It has been previously estimated that at least a quarter of the global burden of disease may be attributable to poor environmental conditions (25 per cent of all deaths in developing regions and 17 per cent of all deaths in developed regions) (WHO 1996). This, however, was thought to be a conservative estimate due to the lack of evidence for many diseases, and the fact that the causal pathway between disease outcome and exposure is complex.

Among children aged 0–14 years it was estimated that 36 per cent of the disease burden may be caused by environmental factors (WHO 1996), with the highest burdens occurring in sub-Saharan Africa and South Asia, and with respiratory infections and diarrhoeal disease being the largest contributors to the environmental burden and mortality. In developing countries, the environmental fraction of diarrhoea, respiratory infections, and malaria accounted for 26 per cent of deaths in children under 5 years.

The global burden of disease estimates have recently been updated (Murray et al. 2012) and the latest findings indicate a predominance of non-communicable disease risks in 2010 compared with 1990. Nevertheless, still today, pneumonia and diarrhoea are the leading killers of young children, accounting for 29 per cent of deaths among children under the age of 5 years. Nearly 90 per cent of these deaths occur in sub-Saharan Africa and South Asia, reflecting uneven progress in reducing child mortality (United Nations Children's Fund (UNICEF) 2012). Further information

on the relevance of global burden of risk estimates for environmental health practice is provided in Box 11.5.1 and Table 11.5.1.

Without substantially more progress, declines in major childhood deaths will not occur. The MDGs remain unfulfilled for many of these countries. At the same time, rapid industrialization and urbanization associated with increased vehicle and industrial emissions is reflected in extremely high levels of air pollution from multiple sources. This is against a backdrop of continued dependence in many multi-million people crowded cities on dirty fuels for heating and cooking that place human health at risk.

The 2010 global burden of disease estimates provide a sense of where environmental health practice could make a big impact in future. Continued support to improve access to water and sanitation services and a transition to cleaner household fuels is a high priority in much of sub-Saharan Africa and Asia.

It remains a travesty that in 2013, 783 million people still do not use an improved drinking water source, and 2.5 billion do not use an improved sanitation facility, mostly in the poorest households and rural areas; 1.1 billion people (949 million people in rural areas, and 105 million people in urban areas), practice open defecation (UNICEF 2012).

Nearly 90 per cent of the deaths due to diarrhoea worldwide have been attributed to unsafe water, inadequate sanitation, and poor hygiene. In addition, around 3 billion people worldwide use solid fuels as their main cooking fuel (UNICEF 2012). (In 2004, it was estimated that solid fuel use contributed to nearly 2 million premature deaths, nearly half of them childhood pneumonia.) It is to be hoped that the integrated Global Action Plan for the Prevention and Control of Pneumonia and Diarrhoea (GAPPD) will impact significantly on ending these preventable deaths (UNICEF and WHO 2013).

From this it is evident that health, environment, and development problems differ in various parts of the world, as do priorities with respect to their management. There is, however, a need in all situations for decision-makers and the public to have ready

Box 11.5.1 Global burden of risk estimates highlight priorities for environmental health practice

The recent global comparative risk assessment of burden of disease and injury attributable to risks published as part of the update of the global burden of disease study 2010 (Lim et al. 2012) provides new data on major environmental risks. The proportion of deaths or disease burden caused by risk factors was calculated, holding other independent factors constant.

Of the 67 risk factors and risk clusters, several related directly to environmental factors. These include: unimproved water and sanitation (separately for water source and sanitation), air pollution (ambient particulate matter pollution, household air pollution from solid fuels and ambient ozone pollution), residential radon, and lead exposure. On a global basis, there have been shifts in these risks since 1990 suggesting some decline in traditional risks such as unimproved water and sanitation, but increases in ambient particulate matter pollution, ozone pollution, and lead exposure, with declines in household air pollution (Table 11.5.1).

In 1990, household air pollution accounted for 7 per cent of global DALYs and ranked second in leading risk factors. In 2010, household air pollution ranked fourth, accounting for 4.5 per cent of global DALYs. The burden attributable to ambient particulate matter pollution has remained largely unchanged (3.2 per cent of global DALYs in 1990 compared with 3 per cent in 2010). Unimproved water and sanitation together accounted for 0.9 per cent of DALYs in 2010 compared with 2.1 per cent in 1990.

These global trends, however, mask major regional differences. Thus household air pollution ranked fourth globally across all risks but ranked first in South Asia, second in sub-Saharan Africa, and fourth in East Asia. Ambient air pollution ranked ninth globally but fourth in East Asia. While unimproved sanitation and water have dropped relative to other risks at a global level (to ranks of 25 and 34 respectively), in sub-Saharan African countries and many Asian countries both still rank around the top ten.

access to accurate information on health hazards associated with environmental risk factors. In the following section we discuss the nature of environmental health effects and factors influencing exposure, and then go on to discuss how environmental health practitioners proceed to assess these.

Environmental health assessment

Nature of environmental health effects

Environmental health practitioners must concern themselves not only with addressing known exposures and disease outcomes associated with these but also, importantly, diseases of unknown cause, with potential environmental links. In addition, still today, for many substances, it is not known whether or not there are safety thresholds for an adverse effect, and, if so, what those levels are.

Certain cancers and ‘subtle’ diseases and conditions related to environmental factors (e.g. lead in relation to intelligence, moderate hearing loss, or raised blood pressure) may not be recognized as such. Thus, the situation remains that much environmental disease goes unrecognized. With regard to chemicals, typically exposures to complex mixtures occur, which have not been well characterized.

Health outcomes

Environmental health effects result from a complex set of genetic, environmental, social, and other factors. Health effects may arise directly from a specific chemical, physical, or biological agent, or indirectly from the broader physical and social environment (e.g. housing, land-use, transport, agriculture, or industry). While as indicated earlier, infectious agents resulting in such illnesses as diarrhoea and respiratory infections may be associated with inadequate water and sanitation and indoor air pollution, non-infectious agents are associated with non-communicable (chronic) illnesses. These include cancers, respiratory conditions like asthma, birth defects, and other illnesses.

Environmental health effects may include minor, temporary ill-health conditions, as well as acute illness and chronic disease. Relatively resistant and susceptible persons may exist at either extreme of the distribution. Effects are frequently irreversible. Acute ill-health effects may follow relatively shortly after an exposure (e.g. poisoning by pesticides, or following a chemical spill), whereas chronic exposure may occur as a result of an individual cumulative exposure over extended periods of time. A long time period may occur between the exposure and the health effect. An example would be asbestos exposure and mesothelioma (Selikoff et al. 1965). Dispersal of the population at risk over time and the long incubation period make it difficult to reconstruct exposures. Some persistent pollutants like PCBs and heavy metals like lead and mercury can accumulate in the environment for years, and may affect people over large distances, causing health effects long after their use has been discontinued. Acute health effects are usually easier to detect than chronic effects, which are difficult to relate to specific hazards or sources.

Multifactorial exposure

In addition, as indicated, many environmental diseases are multifactorial as far as the causal factors are concerned and it may be difficult to determine the effects of one exposure in the light of existence of effects of simultaneous exposure to other factors. Prevention has tended to focus on exposures associated with a single agent or medium (e.g. air or water); however, people are often exposed simultaneously to a wide variety of physical, biological, and chemical agents and may be exposed via several pathways (air, water, food) from one source. As indicated earlier, in developing countries people may be exposed both to hazards associated with poverty (unsafe drinking water and inadequate sanitation), pollution, unsafe agricultural and land-use practices, etc. Relatively little is known, however, of the effects of cumulative exposures and how various risk factors might interact (Tickner 2005).

Also, in dealing with low-level exposures one may deal with factors which play a contributory rather than a primary role, and the co-action of other factors may be needed for an effect to occur. Exposures may be interactive, sometimes resulting in an additive or even synergistic (multiplicative) effect. The risk of health impacts associated with exposure to asbestos, for example, may be significantly increased (multiplied many times) in smokers (Selikoff et al. 1968).

Vulnerable groups

The poor, the elderly, women, and young children may be particularly affected.

The elderly, for example, may be especially vulnerable to some toxic substances which may take longer to eliminate from the body. They may also be more vulnerable to respiratory illnesses associated with air pollution, for example. During pregnancy, women may have altered physiologies and metabolize toxic substances differently, while, during menopause, women may be especially vulnerable, for example, to the release of toxic substances such as lead from bones.

Children are particularly vulnerable to environmental insults (Goldman and Torres 2009). Children are not merely ‘little adults’. They are more exposed than adults, as, due to their rapid metabolism, growth, and development, they drink, eat, and breathe in more of a contaminant relative to their bodyweight than do adults. Children also have enhanced hand-to-mouth activity and

they play close to the ground, increasing their exposures still further. In addition, they have immature, and therefore vulnerable, physiologies. The unborn fetus may be especially vulnerable to toxic chemicals.

Thus different groups have differing vulnerabilities and susceptibilities, including genetic dispositions, nutritional status, health, and physiological status which may influence their exposure (and response). Gene–environment interactions are known to be of importance and different subsets in the population may have different exposure–effect relationships. People may be more or less vulnerable at various stages of their lives.

To intervene on the causes of disease thus requires a good understanding of the health risks and their causes, as well as the susceptible individuals/population, so that surveillance and monitoring systems can be developed to identify in advance potential problems, thereby enabling effective interventions to be designed and implemented.

Role of epidemiology and toxicology

An important part of the work of the environmental health practitioner involves assessing the risks to which people may be exposed in the environment. While there is less uncertainty today about the extent of both direct and indirect risks to human health which are associated with factors in the environment, nevertheless there is still much to be learned about the way in which the environment influences human health.

In conducting health assessments, it is necessary to establish the nature of exposure and health outcome relationships, and to assess causality. Of the various fields that contribute to environmental health (e.g. environmental science, chemistry, physics, engineering, medicine, and many others) of key importance are epidemiology and toxicology, as well as exposure assessment.

Environmental epidemiology is concerned with the distribution and determinants of ill health effects in human populations at risk from environmental exposures. As workplace exposures have decreased over time, and environmental exposures have increased, an appreciation of the multiple causation of disease has grown. Various types of study design have been used in environmental epidemiology to assess the nature of the relationship between an exposure and health outcome(s) in a particular setting or population group. These include ecological studies, cross-sectional studies, case–control studies, cohort or follow-up studies, and intervention studies. They can be challenging to conduct due to the complexity of the health risks and exposures involved, and the need to take into account all the potential sources of confounding (extraneous factors associated with the outcome of interest) and bias.

No matter how well designed and executed, however, epidemiological studies disclose health risks only after exposures have occurred. Also, it is sometimes the case that there is too narrow a range of exposure for epidemiological studies to detect health effects in populations. In addition, it is difficult to measure exposure at the individual level (air pollution is an example) and exposure measurements made at an area or neighbourhood level may sometimes be (incorrectly) presumed to relate at an individual level, leading to what in epidemiological terms is referred to as the ‘ecological fallacy’. This is where inferences about individuals are based on inferences about groups. Thus within an ‘exposed’ area, owing to micro-variations in exposure and other factors

affecting people’s exposure (e.g. behaviour patterns), people may not be homogeneously affected, but be assumed to be so.

Toxicological studies, which are experimental studies of the effect of pollutants on human beings or animals under controlled conditions, are also needed in order to identify in advance any adverse effects of substances under investigation. These have the benefit of allowing for a wider range of exposures to be assessed and can take account of the problem of confounding factors in epidemiological studies. However, extrapolation from laboratory animals to humans, at high to low doses, is complex with many assumptions involved. And it is not usually possible to reproduce all the contributing factors in the laboratory.

While there exist internationally harmonized guidelines for toxicity testing such as those established by the Organisation for Economic Cooperation and Development (OECD), specific testing for toxicity varies by country and depends on the type of substance and the statute under which it is covered. In the United States, for example, pesticides in food require tests of acute and chronic toxicity, neurotoxicity tests, cancer bioassays, tests of reproductive and developmental toxicity, and others (Goldman and Torres 2009).

Making causal inferences

The concept of risk is linked to that of causation. From the previous discussions it is evident that the relationship between many environmental exposures and health outcomes is complex. Even under optimal conditions and with the best study designs, it is difficult to make definitive assertions regarding causality.

Bradford Hill (1965) listed the criteria shown in Box 11.5.2 as being key to assessing whether an observed association is likely to be causal or not.

Risk assessment

While epidemiology and toxicology are used to generate new evidence on health effects, risk assessment too relies on science-based information but synthesizes *existing* information and weighs it up with the aim usually of addressing a particular regulatory or policy issue aimed at reducing or eliminating the risk (Bartel 2005). In this respect the National Research Council (NRC) has referred to it as a mixture of ‘science and judgment’ (NRC 1994).

Risk assessment is used in many fields, including environmental health. It is concerned with the process of estimating, usually in quantitative terms, the harm that will result from exposure to an environmental hazard (Fiorino 1995). Risk assessors might, for example, want to analyse the risks associated with being exposed to an indicator like indoor air pollution, to a specific agent like lead in paint, or to a suspected contaminant in food or drinking water.

The conceptual framework for risk assessment was set out by the NRC in 1983 (NRC 1983) and divided the process into four key elements: hazard identification, dose–response assessment, exposure assessment, and risk characterization. Risk is a function of hazard and dose. *Hazard identification* concerns the identification of environmental agents and health effects for assessment, based on evidence for causality from epidemiological and toxicological studies (see Chapter 7.5). *Dose–response* assessment describes the quantitative relationship between exposure and disease based on models that predict the level of response from any dose. *Exposure assessment* involves estimating or measuring the magnitude,

Box 11.5.2 Criteria for causality

The strength of the association refers to how large the effect or the size of the association is—a strong association (as measured by a relative risk or odds ratio) is more likely to have a causal component than is a modest association. Absence of a strong association does not, however, rule out a causal association. In environmental epidemiology frequently one is dealing with relative risks in the range of 1–2—since they often apply to the general population, however, the attributable risk or public health impact in terms of the absolute number of cases can be large.

Consistency refers to a relationship that is observed repeatedly in different settings using different methods—for example, in differing groups, places, circumstances, time—by others. Finding an association consistently using different study designs, methods, and so on reduces the probability that an association is due to an error in the study design.

Specificity refers to an association that is specific for an outcome or group of individuals—that is, altering only the cause would alter the effect. An example would be mesothelioma in relation to asbestos exposure. Due to the multifactorial nature of many environmental diseases, this is not normally the case, however.

Temporality implies that the factor must precede the outcome it is assumed to affect. This is a critical factor in assessing causality.

Biological gradient refers to a dose–response relationship between the exposure and the disease. An increasing amount of exposure increases the risk.

Biological plausibility is concerned with the extent to which the association is consistent with what is already known about the response to the exposure and/or disease—that is, does it make sense?

Coherence of evidence implies that the causal association should not fundamentally contradict present substantive knowledge.

Experimental evidence stresses that causation is more likely if evidence is based on randomized experiments.

Reasoning by analogy implies that for analogous exposures and outcomes an effect has already been shown. For example, is the observed association supported by a similar association?

Source: data from Hill, A.B., The environment and disease: association or causation?, *Proceedings of the Royal Society of Medicine*, Volume 58, Issue 5, pp. 295–300, Copyright © 1965.

duration, and timing of human exposure to the agent of concern. It necessitates defining the exposed population and the routes of exposure. The final step is *risk characterization*. Information from the previous three steps is combined and the level of response for the identified health effect(s) at the particular level of exposure to the agent(s) in the defined population is estimated.

Tools to aid decision-making

While obtaining knowledge on various risks is fundamental to the practice of environmental health, it is equally necessary to put in place adequate health and environment surveillance and monitoring systems to assess environmental health conditions. In the following sections we deal with the need to develop indicators for health and environment, and with health impact assessment procedures, which have become critical tools to aid decision-making in environmental health.

Indicators

Monitoring systems

Surveillance and monitoring systems of potential hazards, exposures, and diseases exist in various settings, and have been used for differing purposes. Examples include air and water pollution monitoring, blood lead monitoring programmes, poison centre surveillance, and birth defect registries. The blood lead monitoring programme conducted by the US Centers for Disease Control and Prevention (CDC) played an important role in assessing how blood lead levels in the US population fell in association with reductions in the lead content of petrol during the 1980s at a time in which there was much scepticism in many quarters about the role that lead in petrol played in influencing blood lead levels (Goldman and Torres 2009). This shows how essential it is that

information systems are developed that are supportive of policy and decision-making.

From the perspective of environmental health, of key importance is that the exposure information collected is relevant to health concerns, and not merely to monitor the effectiveness of environmental control measures. Frequently it is the case that exposure information is based on data from high-exposure areas obtained for the purpose of assessing compliance with legislated exposure limits. Such compliance-oriented methods are not optimal for accurate estimation of likely exposure levels of the population.

For many pollutants there is a sharp decrease in concentration levels as one moves away from a source. Similarly, significant vertical variations may occur in the concentration level of a pollutant. Knowledge of spatial and temporal variability of concentrations of exposure may therefore be important from a health point of view, and it may also be necessary to take into account that the exposure may be mediated by more than one environmental pathway. Also of relevance is that health and environmental data from monitoring programmes are frequently available at differing levels of resolution, making it difficult to determine any associations. The complexity and intersectoral nature of environmental health surveillance can thus prove very challenging, and few routine monitoring systems are set up to assess exposure to potential contaminants comprehensively.

Role of indicators

Increasingly, however, communities are demanding access to relevant information on the state of the environment and its influence on health, sometimes as part of their ‘right to know’ (pollutant release and transfer registries exist in many parts of the world). With an increasing array of information available (of varying quality and usefulness), there is a growing need for

scientifically sound and useful information to be obtained and made accessible to decision-makers and the public alike. The development of indicators is of importance in this regard, and environmental health practitioners have an important role to play in their design and use.

The Oxford Dictionary defines an indicator as ‘providing specific information on the state or condition of something’ (Oxford Dictionaries n.d.) They are a way of ‘seeing the big picture by looking at a small piece of it’ (Plan Canada 1999). While much information may be available from existing monitoring systems (notwithstanding their shortcomings), if useful indicators are determined in advance, it may be possible to incorporate their data requirements into the information system. As the raw data may not always be in a form which is useful from the point of view of decision-making, indicators can play a key role in turning it into useful information, thereby giving it added value, and also, importantly, in simplifying it. They can give a snapshot (synthesis) view of environment and health trends and can be used to track progress, to help build the evidence base for effective policies, to identify issues and priority problems, provide data for the development of interventions, and for their evaluation.

Indicators have been used in many different fields, at the global, regional, national, local, and sectoral levels. The UN system has been actively involved in indicator development for many years, and there exist numerous data sets on indicators of health, environmental health, environment, sustainable development, poverty, housing, urban development, and others (von Schirnding 2002b, 2007). Indicators have also been applied and developed in various settings and sectors, and have been used in different ways for various purposes, including in ecosystem health, health promotion, healthy cities, and countless other ways (Cheadle et al. 1992; Takano and Nakamura 2001; von Schirnding 2002b).

Types of indicators

Descriptive indicators may be used to highlight what is happening to the environment or to human health, in order to assess trends, and to obtain baseline information on which to formulate subsequent policy options and plans. Examples would be ‘ambient concentration levels of sulphur dioxide in an area’, ‘infant mortality rate’, ‘percentage of the population using biomass for cooking or heating’, ‘incidence of acute respiratory infections in children under five’ or ‘proportion of the population living in informal settlement areas’.

They may be of use at a local level (pollution concentration levels), at a national level (mortality rates, incidence of food poisoning), or at a global level (temperature increases in relation to climate change). A performance indicator on the other hand is one that is linked to a reference value or policy target, illustrating how far the indicator is from the desired level. Examples would be ‘the proportion of the population living in electrified areas’, ‘the number of children immunized against infectious diseases’ or ‘the proportion of food outlets inspected in an area’.

Composite indicators may be developed, which condense a wide range of information on different but related phenomena into a single measure or index. In the field of health, the disability-adjusted life year (DALY) is an example of a composite measure of the burden of disease which combines the years of healthy life lost due to premature death, disability or disease. Gross national product (GNP) is another example of a composite indicator, as

is the Human Development Index (HDI) which combines information on life expectancy at birth, education level, and income level. These demand high levels of statistical and measurement competence in weighting and combining various variables, and may be difficult to interpret depending on how the components are chosen and weighted, which might be somewhat subjective. They are nevertheless useful for summarizing data and for drawing comparisons between countries.

Indicators have an especially important role to play in the context of the planning process (Plan Canada 1999) and setting goals and targets, which need to be measurable.

There are many examples of goal setting in the area of environmental health at all levels—global to local. One example at the global level would be the MDGs (Sachs and McArthur 2005). For example, Goal 7 of the MDGs is: ‘Ensure environmental sustainability’. The target is: ‘To halve, by 2015, the proportion of people without sustainable access to safe drinking water and basic sanitation’. Associated indicators are: ‘Proportion of population using an improved water source’, and ‘Proportion of population using an improved sanitation facility’. Indicators have also been used in health and environment planning processes at the national and local level. In this respect it is important to emphasize that even the best set of well-developed indicators can fail to meet their objectives if they are unrelated to a methodical planning process (Brugman 1997). Indicators should be applicable to the users, rather than being merely technically relevant to data providers. In fact indicators may be derived by community groups and used for community-based monitoring.

Indicator development

The process of indicator development includes defining the characteristics to be measured, identifying the target audience and the purpose of the indicator, choosing a suitable framework, defining criteria for selecting the indicator, identifying and evaluating the indicator, pilot testing, and choosing the final indicator or indicator set (Plan Canada 1999). Criteria which have been developed to guide the development, selection, and evaluation of indicators include such factors as their general relevance, scientific soundness, and their applicability to users. Ideally they should be credible, unbiased, and representative of the condition of interest, as well as be consistent, comparable in different settings in time and space, and readily understandable, based on information that is easily accessible. The definitions used for the indicators should be clear, and the data sources and methods used for their collection should be specified (Kjellstrom and Corvalan 1995).

All potential major sources of information relevant to the chosen indicator should be identified. In many countries, despite inevitable problems related to data quality and coverage, and the limitations of routine monitoring systems, it is nevertheless usually possible to find some basic data of use, even if rudimentary or incomplete. If data on health outcomes and exposures is truly unavailable/unusable/inaccessible, it may be prudent to focus instead on action indicators. It may also be possible to use proxy measures of actual exposure (e.g. in relation to air pollution) like traffic volume, distance from a road, proximity to industry, and so on.

Many sources of information can be consulted, including routine data collected and published by government departments and agencies, universities, research organizations, community-based

organizations, monitoring groups, industry, and the private sector. On a global (and national) basis, data collected by international organizations, and the UN system, including the WHO, the United Nations Environment Programme (UNEP), the UNDP, and UNICEF, can be useful.

Sometimes it may be necessary to focus on sentinel diseases, that is, diseases that may be indicative of an environmental problem (e.g. diarrhoeal disease, acute respiratory infections, acute poisonings, rare cancers). One data source on environmental health effects is the WHO's Environmental Health Criteria series. These documents provide critical reviews of the effects of chemicals, or combinations of chemicals, and physical and biological agents on human health and the environment. Two series are available, one on chemicals, and one on risk assessment methodology (WHO n.d. a). There is also the UNEP's International Register of Potentially Toxic Chemicals (UNEP n.d.), the WHO's guidelines on air and water quality (WHO n.d. b), the International Agency for Research on Cancer's (IARC's) monographs on evaluation of carcinogenic risks of chemical substances (IARC n.d.), and many others.

Indicator frameworks

Several indicator frameworks have been developed for presenting the various linkages between factors under consideration. One of the earliest of these, upon which many others have been subsequently based, is the OECD Pressure-State-Response (P-S-R) Framework (OECD 2001) which looked at the various pressures which impacted on the state of the environment and necessitated various policy responses.

Modifications to this model such as the D-P-S-I-R (driving forces, pressure, state, impact, response) model adopted by the European Environment Agency made provision for broader driving forces to be taken account of, as well as impacts (including on health) deriving from changes to the state of the environment. The WHO's 'DPSEEA' model (driving force, pressure, state, exposure, effect, action) divides the 'impact' component further into exposure and health effects separately (Kjellstrom and Corvalan 1995; von Schirnding 2002b).

Thus, for example, if applied in environmental health, one can think of 'driving forces' as including such indicators as the population growth rate, or the level of economic development, while the resulting 'pressures' which may be exerted on the environment may be in the form of indicators like pollutant emissions. This may in turn cause the 'state' (quality) of the environment to be degraded through the dispersal and accumulation of pollutants in various environmental media like air, soil, water, and food (indicators might include pollutant concentration levels in media). People may then become 'exposed' to these hazards in the environment (an indicator might be people exposed to air pollution levels above standards) and a variety of 'health effects' may subsequently occur (indicators like air pollution-related morbidity and mortality could be useful). Various 'actions' can then be implemented at different points in the framework (indicators might include clean air policies, technical control measures, treatment regimens or education measures).

While this may be considered a somewhat linear and simplistic model of what is in reality a complex web of circular feedback loops, it can nevertheless be useful for presenting data in a way that shows the linkages between exposures, health effects, and

policy actions in a straightforward and readily understandable, actionable way. The form in which the information is conveyed may have considerable impact on how it is used and interpreted. Nevertheless when it comes to dealing with complex ecosystems, for example, deciding what to measure, and how to measure it, and present it, can be very challenging (Cole et al. 1998). In the realm of climate change, development of indicators of vulnerability and preparedness to inform public health adaptation strategies and project the impact of climate change on human health, is an example (English et al. 2009).

Environmental health impact assessment

It is critical to conduct research on specific hazards, carry out epidemiological studies, conduct risk assessments, do environmental monitoring and surveillance of risks, and develop indicators. Most importantly, it is necessary to prevent risks to human health occurring from the outset. In many countries relatively little attention has been paid to the health impacts of planned developments. This, however, is a critical aspect of the practice of environmental health. Impact assessment provides a powerful (yet under-utilized) tool to institutionalize a holistic, cross-sectoral approach to addressing health in public policy (Bhatia and Wernham 2008).

Key steps

In line with the principle of sustainability, development should minimize negative health impacts and maximize health benefits. Health impact assessment (HIA) is a decision-support tool aimed at adding value to the decision-making process by analysing potential effects of planned policies, programmes, or projects on health (Davenport et al. 2006). It aims to identify and predict the impacts of proposed developments on environmental parameters that have a strong health significance. Using information from epidemiological and toxicological studies, researchers attempt to identify, predict, and evaluate possible changes in health which could occur as a result of the development under consideration. A risk assessment is then undertaken (see Chapter 7.5).

HIA is to an extent based on the environmental impact assessment (EIA) process, with a number of procedural steps accompanied by opportunities for stakeholder involvement. Steps to conduct an HIA include *screening* to identify projects or policies for which an HIA would be useful; *scoping* to identify which health impacts should be assessed and which populations are affected; *assessing* the magnitude, direction, and certainty of health impacts; *reporting* results to decision-makers; and *evaluating* the impact of HIA on the decision-making process. Some HIAs focus on biomedical outcomes (e.g. respiratory disease), while some define health holistically to include social, environmental, and economic conditions. Others focus on equity impacts (Dannenberg et al. 2006).

HIA approaches

Some approaches consider HIA independently of EIA while in other cases HIA is integrated with EIA. For example, in some European countries HIA has evolved independently of EIA and is applied in a wide range of public policy decisions not subject to EIA (Kemmer et al. 2004). Despite much work done over the past years however, in a majority of countries, health impacts are all too infrequently incorporated into the impact assessment process.

In comparison with EIA, HIA is still, in many ways, in a rudimentary phase. This is somewhat surprising given the substantial growth in HIA activity in recent years, as evidenced by the number of publications, training courses, and guidance materials developed (Davenport et al. 2006).

Indeed it is interesting to note that even in the country where EIA originated (namely the United States with the promulgation of the National Environmental Policy Act of 1969 (NEPA 1969), and which established the foundation for environmental policy in the United States)—health impacts are still infrequently incorporated into the EIA process, although this is gradually changing. While the objectives and regulations of NEPA do indeed provide for the protection of human health and welfare, in practice where health impacts have been considered, these have been narrowly focused on chemicals and toxic exposures. A comprehensive and systematic approach to addressing human health impacts in impact assessment procedures has yet to evolve. A range of institutional, organizational, and disciplinary factors may account for this (Rattle and Kwiatkowski 2003).

It is also a consequence of the complexity of relationships between exposures and health outcomes as discussed earlier. Sometimes there may be inadequate evidence and methodological challenges involved in predicting health outcomes and it is necessary to make decisions at the pace required by political or economic priorities, which may be based on existing evidence, albeit flawed or inadequate, and professional opinion.

Some have contended that a voluntary approach to HIA is preferable to a regulatory approach, where there is more procedural rigidity and stricter rules of evidence required (Cole et al. 2004). That said, it is often the case that causal certainty and quantitative precision are unrealistic and unnecessary standards for impact assessment. What seems likely is that HIA linked to EIA will conform to the limits of EIA, rather than HIA expanding the scope of the EIA (Cole and Fielding 2007), although there is some evidence in Canada that there has been some success with expanding the traditional EIA approach.

Need for capacity building

Whatever the case may be, HIA methodology has been criticized for the lack of rigour in its use of evidence, and guidance is needed on the kinds of public health effects to be included in an impact assessment, as well as on the methods for analysing health effects. New analytical tools are needed to translate the impacts presented in an EIA into valid health impact predictions. The scope of health issues that could be addressed is broad, and includes conditions as diverse as traffic injuries, social cohesion, traditional diets, domestic violence, psychological problems, and so on (Bhatia and Wernham 2008).

Impact assessment training for environmental health practitioners should be included in the curricula of schools of public health as well as in continuing education courses. There is only one university graduate school course on HIA in the United States (Bhatia and Wernham 2008). Countries should advocate for formal guidance on incorporating health into EIA. Examples exist in Australia and Canada, where guidance for social impact assessment contributed to institutionalizing these issues as routine considerations within EIA.

A guide to reviewing available evidence for use in HIA has recently been developed by the WHO (Mindell et al. 2010). However, in order for HIA to be more effective, environmental health practitioners need to familiarize themselves with the EIA process and they need also to be more involved in community collaboration (Bhatia and Wernham 2008). In practice, there often exists a tension between the need to involve communities in the HIA process but at the same time to give priority to expert- and research-generated evidence (Wright et al. 2005).

Intersectoral action and partnerships

The previous subsections on indicators for decision-making, and on HIA processes, have highlighted the possibilities for these tools to help institutionalize intersectoral approaches to policy and decision-making. In this section, we discuss the nature of the intersectoral planning process in addressing health and environment concerns at various levels, which is a key aspect of the practice of environmental health.

The intersectoral nature of environmental health is recognized in the WHO's Constitution (WHO 1948), which states that the Organization shall 'promote, in cooperation with other specialized agencies, where necessary, the improvement of nutrition, housing, sanitation, recreation, economic or working conditions and other aspects of environmental hygiene'.

Intersectoral action for health (IAH) has been identified as an important component for achieving the goal of 'Health for All' (HFA) by the year 2000 (WHO 1981). The concept has been developed in a number of international fora, including the Alma Ata conference in 1978 (WHO 1978), the World Health Assembly (WHA) Technical Discussion on Intersectoral Action (WHO 1986a), the Ottawa Charter on Health Promotion (WHO 1986b), the Sundsvall meeting on Supportive Environments for Health (Haglund et al. 1996), in the WHO Commission on Environment and Health (WHO 1992), and at the international conference on 'Intersectoral Action for Health—A Cornerstone for Health-for-All in the 21st Century', held in Canada in 1997 (WHO 1997; Kreisel and von Schirnding 1998).

At this last meeting IAH was defined as 'a recognized relationship between part or parts of the health sector with part or parts of another sector which has been formed to take action on an issue to achieve health outcomes... in a way that is more effective... than could be achieved by the health sector acting alone'.

Addressing the underlying determinants of health is essential in order to ensure long-term health improvements which are sustainable. By addressing health, environment, and development concerns in an intersectoral way a win-win situation occurs: the health sector gains because disease prevention can move upstream and take advantage of the intersectoral approach to development and environmental improvements. The environmental sector gains because environmental issues can become grounded in matters of local and direct concern to people.

Global initiatives

Rachel Carson's book *Silent Spring*, published in 1962 (Carson 1962), was one of the early and most powerful warnings to humanity about the consequences of its actions on the environment. About a decade later the UN Conference on the Human Environment was held in Stockholm, Sweden (UN 1972), which

was followed in 1983 by the World Commission on Environment and Development headed by former Norwegian Prime Minister Gro Harlem Brundtland (World Commission on Environment and Development 1987). This linked the issue of environmental protection to economic growth and development. The Commission's report 'Our Common Future' (World Commission on Environment and Development 1987) launched the concept of sustainable development into the mainstream of world debate.

Sustainable development was defined in the report as 'Development that meets the needs of the present without compromising the ability of future generations to meet their own needs' (World Commission on Environment and Development 1987). It essentially meant meeting people's development needs in such a way as not to exceed the earth's carrying capacity in the longer term. Although specific definitions for sustainable development vary, broadly speaking, the concept is concerned with balancing environmental, social and economic objectives in order to maximize societal well-being, both now and in the future. This has been referred to as the triple-bottom-line approach to human well-being (Sachs 2012).

While subsequent environmental conferences built on this growing recognition of the links between environment and development, the awareness of the links between environment and development is also evident in the public health movement, especially, for example, as highlighted in WHO's 'Health-for-All' strategy in 1977 (WHO 1977) and renewed in 1998 (Yach 1996; WHO 1998) which aimed to achieve for all people of the world a level of health which would enable them to lead 'socially and economically productive lives'.

A key milestone was the Ottawa Charter on Health Promotion in 1986 (WHO 1986b) which addressed the need for a broader understanding of public health beyond primary healthcare and which stressed the necessity to take a more holistic view of health and, among other factors, to develop healthy public policy and create environments which were supportive of health. Strong emphasis was placed on the environmental component of health and to see health in ecological terms.

Significantly, the Ottawa Charter emphasized the importance of actions both outside of, as well as within, the health sector. It also emphasized the need to look at the settings where people lived, worked, and recreated. This was followed up on in a subsequent conference held in 1991 in Sundsvall, Sweden on Supportive Environments for Health (Haglund et al. 1996), which looked at the role of various sectors in influencing health outcomes, serving as inputs for the subsequent UN Conference on Environment and Development held in 1992 (UN 1992).

In parallel with the progressive greening of the public health movement (emphasizing more of a socio-ecological approach), more emphasis has been placed on the human element in recent environmental (sustainable development) conferences. These have been key in fostering intersectoral partnerships to reduce environmental hazards in line with sustainable development objectives.

United Nations Conference on Environment and Development

The UN Conference on Environment and Development (UNCED) (UN 1992)—a watershed event popularly referred to as the 'Earth Summit'—resulted in the adoption of Agenda 21—a global action plan with concrete goals, targets, and outputs for measures needed to achieve environmentally sustainable development into

the twenty-first century. It also resulted in the 'Rio Declaration' which encompassed important agreements on 27 principles adopted by 178 nations (including the Precautionary Principle, and the Polluter Pays Principle), and several key conventions such as those on Climate Change (including the Kyoto Protocol) and on Biological Diversity (and the Cartagena Protocol).

The Rio Declaration, in its preamble, alluded to the central role of health in sustainable development by stating that 'Human beings are at the center of concerns for sustainable development. They are entitled to a healthy and productive life in harmony with nature'. This concept was further developed during the planning process for the World Summit on Sustainable Development (WSSD) (UN 2002) which took place in Johannesburg, 10 years after UNCED.

World Summit on Sustainable Development

At WSSD, health was singled out as one of the five priority issues to be addressed, along with water, energy, agriculture, and biodiversity (Annan 2002; WEHAB Working Group 2002). In the Johannesburg Plan of Implementation (JPOI) which emerged from this conference, particular emphasis was placed on health issues in relation to environment and poverty concerns. Improving access to safe water, sanitation, clean air, improved waste management, and sound management of chemicals were among the key environmental health issues that received special attention in Johannesburg (von Schirnding 2005).

Of particular note was the call to increase access to sanitation to improve health and reduce infant and child mortality, prioritizing water and sanitation in national sustainable development strategies and poverty reduction strategies where they exist. A new target was agreed, namely to halve by the year 2015 the proportion of people who do not have access to basic sanitation. This target complemented the MDG target on access to safe drinking water. Other agreements concerned the safer use of chemicals, reduction of risks associated with heavy metals, reduction of air pollution exposures and related health impacts (through the use of cleaner fuels, modern pollution control techniques, and reduced dependence on traditional fuel sources for cooking and heating), and to increase the global share of renewable energy sources.

There was also a call for capacity building in health to better assess health and environment linkages. Other aspects emphasized in the JPOI included the need to integrate health concerns within strategies, policies, and programmes for sustainable development. Many of the MDGs and targets agreed by world leaders in 2000 were confirmed at WSSD. WSSD was thus an important milestone for health (von Schirnding 2005) which took concerted effort by key players including many countries and the UN system, most notably the WHO (WEHAB Working Group 2002; WHO 2002a, 2002b, 2002c).

United Nations Conference on Sustainable Development (Rio+20)

This momentum was somewhat lost in the subsequent run-up to the twentieth anniversary of UNCED. In June 2012, the world's leaders and 50,000 delegates from 193 countries gathered in Rio to seek a new consensus on global actions to safeguard the future of the planet. 'Rio+20' (UN 2012) aimed to review progress over the past 20 years and to renew political commitments to sustainable development. According to some, however, an important

opportunity for a paradigm shift in international policy was lost (Barbier 2012).

While many new green economy policies were endorsed in the final document ‘The Future We Want’, no new international commitments nor legally binding agreements were made, albeit voluntary agreements were made by countries to meet their own sustainable development targets. Key global health outcomes related to global environmental change were omitted from the outcome document, and in the view of some observers, health was inadequately highlighted as a cross-sectoral priority for sustainable development, with many important linkages to other sectors like energy, biodiversity, land and water management, and climate change largely absent (Langlois et al. 2012). Coming out of WSSD where health made a strong showing, and out of the MDG process where health had a central position, at the very least, the Rio+20 experience confirmed the importance of the health community remaining actively engaged in the sustainable development agenda (Singh et al. 2012).

It should also be pointed out that all three conferences (UNCED with its focus on environment, WSSD with its focus on the social dimension—poverty, and Rio+20 with its focus on the economy) failed to ensure the integration of the three pillars of sustainable development. In addition, the trade-offs and synergies across the economic, environmental, and social objectives have not yet been agreed (Sachs 2012). The process of setting sustainable development goals in the follow-up process to Rio+20 is a way to remedy this, providing the three pillars of sustainable development are not considered separately from each other. Health can be used as a tool to integrate across the three dimensions of sustainable development. Measurable targets are needed to ensure health remains a prerequisite for, and an outcome of, sustainable development—in all its dimensions.

The Commission on Global Governance for Health which was created in 2012 will now emphasize the need to ensure that health is protected and promoted in global policy arenas outside the health sector (Ottersen et al. 2011). As German Chancellor Angela Merkel said in her welcome message to the 2012 World Health Summit held in Berlin (quoting Arthur Schopenhauer) ‘Health is not everything, but without health, everything is nothing’ (Kleinert et al. 2012).

National and local initiatives

Global concerns about the environment have led to common approaches to environmental health planning and policy development and international cooperation in controlling some environmental hazards. While governments share the main responsibility for ensuring healthy living environments, they can do so only by working in collaboration and partnership with other groups. Involving stakeholders in all stages of the decision-making process is an important part of the practice of environmental health. Over recent years there has been an increasing trend towards decentralized government services and more emphasis on health and environmental actions by NGOs and the community itself. Intersectoral, participatory planning has become more central to the way governments do business in the field of environmental health.

Most health and environment action plans that have been developed in countries, involve articulation of a common vision, identification of key issues and their ranking/prioritization,

collection and analysis of data and information, development of a plan of action with goals and targets (and indicators), a resource mobilization plan, and, following implementation, a process of monitoring, evaluation, and follow-up. Sometimes a rational and comprehensive process will have been put in place while in others planning will have been done in a more incremental way.

Where partners have been involved in the definition of problems as well as in their solution, there has been a better chance of commitments being met in the long term. Identifying the right partners has proved to be a critical step, as this plays a key role in determining the legitimacy or otherwise of the planning initiative. In general, success has been achieved in situations where all partners have an interest in the problem and are interdependent in reaching solutions (Box 11.5.3). Service users and providers are normally represented, as well as other interested and affected parties and parties with particular knowledge and expertise. Groups such as business and industry, local, national, and regional government, trade unions, community groups and residents, women’s groups, youth groups, and the media might commonly be represented.

There have been a number of collaborative planning initiatives at various levels of government which involve partnerships with NGOs and local communities, whereby health authorities have been able to address problems more effectively. For example, there have been the national environment and health action plans at the national level and local health and environment planning initiatives such as local Agenda 21 initiatives, and initiatives like the WHO healthy cities movement, the UN Human Settlements programme, and UNEP’s sustainable cities movement (von Schirnding 1997a).

These have led to a better understanding of the importance of environment and development issues within health ministries, as

Box 11.5.3 Ingredients for successful partnerships

Among the key ingredients for a successful partnership are the following:

- ◆ The contributions of all partners should be understood and valued.
- ◆ The core interests of individual organizations should be protected.
- ◆ Partners should be able to gain resources and/or legitimacy.
- ◆ There should be opportunities for action and capacity for action.
- ◆ There should be a clear mandate and authorization from the government body concerned.
- ◆ Agreement should be reached on how results will be acted on.
- ◆ There should be a clearly defined decision-making process.

Box 11.5.4 United Kingdom National Environmental Health Action Plan

The UK National Environmental Health Action Plan, intended to improve environmental health in the United Kingdom, set out ways in which improvements could be made and identified the sectors responsible. It contained more than 160 actions with a checklist against which progress could be measured. In drawing up the plan the views of a wide range of people and organizations were taken into account. Five areas were set out in the plan, namely institutional framework, environmental health management tools, specific environmental hazards, living and working environments, and economic sectors. The objectives, bases for action, and actions were set out for each of the areas covered by the plan. These were divided into three types according to their urgency, namely basic requirements, prevention and control of medium- and long-term hazards, and promotion of well-being and mental health. The plan gave both an overview of the provision of environmental health and a detailed analysis of the main factors contributing to it, setting out a range of specific actions which may be needed to improve it. In this way the means of achieving the objectives of the plan were established.

well as a better understanding of health issues within environment ministries. In many cases successful intersectoral committees or commissions and fora have been set up, and in the process alliances and linkages formed with various sectors. Linkages with the finance and planning sectors, however, have frequently been among the weakest of these.

On a global basis, approaches to incorporate health and environment issues in national plans and programmes have varied from country to country depending upon priorities and planning mechanisms and the way in which responsibilities are divided. This has led to a wide variety of approaches being adopted (Box 11.5.4).

Sometimes health and environment plans have been included in the national plans for sustainable development or for economic and social development. Sectoral plans might include health and environment issues or health considerations might be included in national environmental action plans and so forth.

Healthy cities

The healthy cities project has been instrumental in helping to address health and environment issues at the local level in many countries and settings. What started as a small-scale initiative of the WHO arising from the Beyond Healthcare conference held in Toronto, Canada in 1984, became a major movement involving thousands of cities throughout the world.

The healthy cities concept and approach has been translated in different ways according to different priorities and emphases of different localities: healthy cities in Europe and Africa, healthy islands in the Western Pacific region, healthy municipalities and communities in North America, healthy villages in the eastern Mediterranean, as well as healthy settings which encompassed schools, homes, and other settings where people live, work, and recreate (von Schirnding 1997b).

Importantly, the healthy cities movement emphasizes process—in particular the building of political commitment and a common vision locally to push health higher up the urban policy agenda. Secondly, there is involvement of a wide range of stakeholders including local communities, and emphasizing community empowerment and participation rather than an expert-led health agenda. Thirdly, strategy development within local government, in the form of a city health plan based on intersectoral partnerships and the necessary stakeholder engagement, is important. This goes along with the development of health information systems, the integration of health into other urban policy and planning processes, and the use of tools to assess health effects (Rydin et al. 2012).

In a review of the healthy cities project in Europe (WHO Regional Office for Europe 2008) a majority of cities were found to be implementing collaborative plans, projects, or programmes with greater cross-sector involvement. Most had developed city health plans and city health profiles, although health-effects assessments were often lacking. Implementation of these intersectoral policies, however, has proven more difficult than expected. According to the commission by *The Lancet*, most cities evaluated are still struggling with the holistic approach in which health is fully integrated into urban planning. This is no doubt in part due to lack of adequate understanding of the complexity of systems at work in these urban settings, prompting utilization of a systems approach to the analysis of healthy cities in the future (Rydin et al. 2012).

Of key importance though, is that the health sector fit in with planning processes in other sectors rather than the other way around. This is especially true of the healthy cities movement if it is to be more than merely a health promotion, awareness-raising initiative. As we have seen in other areas like HIA, the health sector is also frequently lacking the expertise and capacity needed to measure or estimate the health impacts associated with proposed projects or policies. Until it has developed that capacity its ability to meaningfully participate in intersectoral work may be limited. What is needed is to be able to better characterize the health burden from the perspective of the sector, rather than the specific vehicle of exposure—for example, air or water.

While the national and local intersectoral health and environment planning processes have been useful in obtaining a better understanding of the nature and causes of environmental health problems in various countries, problems and weaknesses have been identified including: gaps in data availability and quality, difficulties in detecting trends (geographical and temporal), difficulty in disaggregating data, poor linkages of health and environmental data, and sectoral data, emphasis on symptoms rather than on causes of problems, little focus on analysis of management structures and capacity, and lack of clarity in priority-setting processes. Many of these issues have been discussed in earlier sections. Environmental health management issues are further elaborated on in the following section.

Environmental health management and policy

While there is more acceptance now of the links between health status and the determinants of health, especially those that arise from the activities of sectors other than health, there are still problems acting on this knowledge. Greater attention needs to be

paid to developing institutional, managerial, administrative, and financial capacities to address problems. Definitions of environmental health aside, it has become increasingly complex to define roles and responsibilities in environmental health in light of its inherent intersectoral nature.

The Institute of Medicine (IOM) report *Investing in a Healthier Future* (2012) came up with the recommendation that it is of critical importance to develop a detailed description of a basic set of public health services that must be made available in all jurisdictions. They developed the concept of a minimum package of public health services which includes foundational capabilities and basic programmes which no health department can be without. These apply regardless of the specific area of control—for example, whether it be infectious disease control or environmental health. They are capabilities that are needed across all programmes.

Some of these foundational public health capabilities defined by the committee include the following:

- ◆ Information systems and resources, including surveillance and epidemiology.
- ◆ Health planning (including community health improvement planning).
- ◆ Partnership development and community mobilization.
- ◆ Policy development, analysis, and decision support.
- ◆ Communication (including health literacy and cultural competence).
- ◆ Public health research, evaluation, and quality improvement.

The committee also made recommendations on basic programmes which are activities that no well-run public health department can be without. High-level categories of basic programmes include maternal and child health promotion, injury control, communicable disease control, chronic disease prevention, environmental health, and mental health and substance abuse.

When it comes to managing environmental health issues which are intersectoral and whose determinants frequently lie outside the control of the health sector, or outside of jurisdictional boundaries, with different organizations and agencies having differing roles and responsibilities, things become complicated. In addition, systems of organization in many government authorities worldwide may be based on concepts of bureaucracy, hierarchy, professional authority, disciplinary specialization, and sectoral analysis (von Schirnding 1997a). To facilitate implementation of intersectoral plans there may be a need for institutional restructuring and readjustment.

This may include internal reforms within government departments. Issues that may need to be addressed might include mechanisms for interjurisdictional cooperation in implementing policies and plans, decentralization of structures to facilitate community involvement of sectors, and better coordination between and within governance structures. Various types of jurisdictional reform can take place, which might include the transfer of powers and functions from one department to another or from one tier of government to another, or changing geographical boundaries, consolidating multiple jurisdictions, forming various coordinating mechanisms, and so on. Thus many barriers and obstacles need to be overcome in coordinating action between sectors. Sharing power, information, and financial resources are all important.

Environmental health services

While there is no universal understanding of what precisely constitutes an environmental health service, it is essentially concerned with developing and implementing environment and health policies, largely through monitoring and control activities, but also increasingly through environmental health promotion efforts. Environmental health services worldwide have been established and developed within a complex framework of policies, institutions and legislation. The concept of environmental health, the problems to be addressed, the way in which services are delivered, and the way in which governments are organized differ considerably throughout the world.

Environmental health activities are carried out in many different settings at various tiers of government, in the private sector, the workplace, healthcare facilities, and so on. In most countries a range of different agencies have responsibility for various aspects of environment and human health at different levels of government. Normally there are separate regulatory agencies dealing with the environment, health, food safety, agriculture, and so on, which have various environmental health responsibilities. Different tiers of government have different responsibilities. Thus, for example, regulatory frameworks and standards (e.g. for air, drinking water, etc.) may be set at a national level, while implementation and enforcement may occur at a state, regional, or local level. Inspection of food preparation premises, food hygiene, sanitation, vector control, and so on, are normally done at the local level. This requires strong monitoring and enforcement abilities which are sometimes in short supply, especially in some developing countries (see Table 11.5.2).

Internationally a shift has occurred towards organizational diversification regarding environmental health services. In the context of the development of primary healthcare services and district health systems in many developing countries, and parallel development outside of the health sector of environmental management systems, the placement of environmental health services is a fundamental issue in need of addressing. Despite the fact that environmental health is recognized as a major and core function of a public health department, it is also the case that the public health sector has gradually lost organizational responsibility for many aspects of environmental health.

This includes, increasingly, such aspects as air quality, waste management, chemical safety, meat inspection, and many other areas. While it would be unmanageable for the full ambit of environmental health services to be located centrally in one department, in light of its intersectoral nature, what is needed is to

Table 11.5.2 Examples of environmental health concerns at local, national, and global levels

Local	Regional/national	Global
Dust control	Hazardous waste	Climate change
Noise control	Air quality standards	Transboundary pollution
Solid waste	Water quality standards	Ozone depletion
Sanitation	Regulation of toxic chemicals	Marine pollution
Vector control	Food safety policy	

Box 11.5.5 Organizational responsibility for environmental health in the United States

In the first part of the twentieth century in the United States, a typical scenario was a health department headed by a physician, with nurses responsible for immunization programmes and sanitarians/sanitary engineers responsible for sanitary inspection, water and sanitation, food safety, vector control, and so on. Sanitarians were generalists trained to respond to a broad array of environmental health issues.

With increasing industrialization and growing public awareness about the widespread contamination of the environment in the 1960s, a number of environmental laws dealing with water and air quality, toxic substances, and other issues were passed and the US EPA was established. Separate state-level environmental agencies were also established, with responsibility for enforcement of these new environmental laws. At this time many of the traditional environmental health functions falling under health departments were transferred to environmental departments with positive (increased funding and visibility) but also negative (schism in environment and health actions) repercussions. Separate data systems, uncoordinated planning, and loss of oversight of community health and environment issues resulted. With the new environmental 'medium-specific' laws, and the emergence of environmental health specialists in particular areas like water or air quality, environmental health professionals became increasingly disconnected from their public health roots and counterparts in health departments at state or local level and the agencies grew apart too.

Subsequently in the 1970s and 1980s there was a growing public awareness and involvement in environmental health issues and a demand for more accountability and transparency in decision-making. With the advent of environmental impact assessment legislation and requirements for public involvement, watchdog groups and advocacy organizations were formed with a strong focus on environmental justice, human rights, and equity concerns. Increasing initiatives to reconnect environmental and public health sprang up out of a sense of growing dissatisfaction over the inability of accountable agencies to address these in a coordinated and integrated way.

Source: data from Kotchian S., The practice of environmental health, pp. 895–925, in Frumkin H., (Ed), *Environmental Health: From Global to Local*, Jossey-Bass, San Francisco, USA, Copyright © 2005.

develop organizational structures that facilitate the movement of professionals across different departments, sectors, and organizations. Box 11.5.5 gives a case study from the United States, which is typical of the situation in many countries around the world, who face similar challenges in regard to the placement of environmental health functions subsequent to the establishment of environmental departments and new environmental regulations.

Environmental health practitioners

In general, environmental health practitioners and professionals have as their main responsibilities the identification, assessment, management, communication, and remediation of health risks resulting from environmental factors. They include people working in a wide range of professions and specialties and include environmental health officers (EHOs), sanitarians, health inspectors, clinicians, epidemiologists, toxicologists, environmental scientists, environmental engineers, veterinarians, and many others.

Environmental health officers

As stated at the beginning of this chapter, the roots of the environmental health profession today can be found in the sanitary and public health movement of the United Kingdom during the 1800s. The role of the health inspector has steadily changed over the years and has evolved from a focus on inspection and control to a role associated as well with education, health promotion, and community development. Commensurate with the changing role of the health inspector has been a change in title—variously referred to over time and in different settings as sanitarian, inspector of nuisances, sanitary inspector, health inspector/technician/assistant, public health officer, environmental health officer, environmental health practitioner/specialist/professional.

Notwithstanding changing roles and titles, the theory and conceptual basis of environmental health is firmly based in public health, and the practice of environmental health, as embodied in the day to day work of EHOs and others, is closely associated with

inspection and environmental control, with EHOs being responsible for administering and enforcing legislation related to environmental health.

Nonetheless, with the increasing involvement in environmental health of professionals and specialists from a wide variety of fields including environmental chemistry, physics, environmental science, geography, environmental engineering, public health, medicine, and others, the role of the EHO outside of its traditional ambit of inspection, monitoring and control, will continue to evolve. This also has a bearing on their role inside of, and outside of, the health service, and the challenges and constraints faced while working on the broader determinants of health, within the principles of sustainable development, but remaining firmly public health based.

Normally an EHO would be a public employee in a health department in local government or at regional/provincial/state level who investigates environmental hazards and public health nuisances with the view to mitigating or eliminating these. EHOs are involved in inspection of housing, food establishments, schools, daycare centres, nursing homes, and many other premises, and are also involved in vector control, pollution control, and health promotion activities. They may also be employed by the military and by the private sector.

Qualifications and training

Environmental health requires, in many countries, a university degree, with field training and professional certification needed for environmental health officers/practitioners. In the United Kingdom, a degree in environmental health is required, as well as certification and registration with the Chartered Institute of Environmental Health. Fourteen universities in the United Kingdom offer accredited environmental health degrees, including undergraduate and post-graduate degrees. A post-graduate environmental health qualification is required for graduates from other scientific disciplines (Chartered

Institute of Environmental Health n.d.). The Chartered Institute of Environmental Health offers training modules in specialized areas of environmental health as does the Environmental Health Registration Board (n.d.).

In Canada, environmental health officers require a bachelor's degree in environmental health or a related field as well as a certificate in public health inspection. Five universities in Canada offer degree programmes approved by the Canadian Institute of Public Health Inspectors (n.d.). A bachelor's degree and professional licence is also a requirement in parts of the United States and there exists the National Environmental Health Association (NEHA) offering environmental health credentials and registration/certification for practitioners. Interestingly, the premier NEHA credential is referred to as the Registered Environmental Health Specialist/Registered Sanitarian (REHS/RS) (NEHA n.d.).

There exists too the International Federation of Environmental Health (n.d.) to promote cooperation between countries where environmental health issues are cross-boundary. Regional groups exist in Africa, the Americas, Asia and the Pacific, Europe, and the Middle East. Member countries in turn have their own professional institutes and associations of environmental health. These include such bodies as the Environmental Health Workers Association of Uganda, the Public Health Inspectors Union of Sri Lanka, the Malta Association of Environmental Health Officers, the Kenya Association of Public Health Officers, and numerous others, reflecting the variety of names given to those practising environmental health around the world.

In a developing country such as South Africa, degree courses in environmental science or health are offered at universities and diploma courses (e.g. the National Diploma in Environmental Health) at technical institutions. Degrees in technology in environmental health are also offered. Environmental health practitioners require practical training and registration with the Health Professions Council of South Africa (n.d.).

Training programmes have been updated to accommodate the changing role of the environmental health officer in South Africa from law enforcer to community facilitator, in line with changing political and economic realities which make legislation difficult to enforce, especially in the context of rapid urbanization, informal settlements, and a large informal sector.

Clinicians

Clinicians are becoming increasingly involved in the practice of environmental health. The diagnosis of illnesses that are associated with environmental exposures is an important clinical function that expanded from the field of occupational medicine, to a focus on the broader environment outside of the workplace (Laumbach and Kipen 2005). Treating environmentally related diseases is often the same as treating these illnesses from other causes, although in some cases (e.g. lead poisoning), specialized treatments may be required. Clinicians need to be alert to the role that environmental factors may play and adopt a high 'index of suspicion' in assessing underlying signs, symptoms and diseases in patients—whether adults or children (Laumbach and Kipen 2005).

If an environmental cause is suspected, an environmental history would need to be taken in order to obtain information on potential sources and pathways of exposure (both current and past), and the age and development stage of children, should they

be assessed. In the case of infants, for example, breastfeeding could be a source of exposure to be considered, and the hand-to-mouth pathway could be of special significance.

Examples of environmental health problems dealt with by clinicians include lead poisoning, asthma associated with air pollution, poisoning by pesticides, hearing loss caused by noise, cancer associated with excessive radiation, and many others. Apart from diagnosing and treating environmental diseases, clinicians also have an important role to play in prevention, including advocacy for protective standards, and patient education.

Children's environmental health issues have become of increasing importance to paediatricians. In 1997, an Executive Order on Children's Environmental Health and Safety was signed in the United States and a cabinet-level oversight committee was formed between the US EPA and the Department of Health and Human Services. Since then, children's environmental health has become an increasingly important part of paediatric practice. Improved exposure and risk assessment and toxicity testing is needed to more adequately address children's environmental health issues, however (Galvez et al. 2005). As part of the WHO's contribution to the follow-up to the WSSD held in 2002, an international alliance on 'Healthy Environments for Children' (HECA) was formed to help advocate for worldwide action on environmental health issues affecting children (WHO n.d. c).

Environmental health policy

Environmental health policy is concerned with selecting actions to reduce or eliminate harmful effects of environmental exposures. Some measures may be short term and remedial while others may be preventive and longer term. Actions can take many forms and involve such factors as regulations and standards, technological control measures, product design, personal or community protection measures, health and environment action plans, housing or transport policies, awareness raising, and education measures and so on. They can take the form of standards that directly regulate the amount of a contaminant in an environmental media, for example, an air pollution standard or drinking water standard. Other policies can benefit health more indirectly, for example, an environmental protection measure that safeguards biodiversity, or a policy in a sector like energy which may determine which fuels are used, and hence their impact on air quality and health.

By better aligning the policies of sectors with the potential to affect health we can maximize opportunities for health. Thus health professionals need constantly to motivate for policies that are beneficial to health—for example, food and agricultural policies that promote integrated vector control over use of toxic chemicals, that encourage substitution of crops that harm health, and that promote consumption of diets balanced in fruits and vegetables. Similarly energy policies need to support clean energy sources, cleaner and more energy efficient transport, and energy efficient buildings while transport policies need to encourage use of bicycles and public transport, and so forth.

The overall cumulative impact of such policies can be substantial. This would also help ensure that health does not become sacrificed for short-term sectoral or economic gain. That is not to imply that health and environmental goals always coincide—frequently they do not. DDT is one example where the immediate health gains were used to lobby for its continued use in sub-Saharan

Africa despite its longer-term insidious negative impact on the environment.

Some laws and regulations may in turn contain policies embedded in them. For example, NEPA in the United States states that 'Congress recognizes that... each person should enjoy a healthful environment and that each person has a responsibility to contribute to the preservation and enhancement of the environment' (Johnson 2005).

Federal laws form much of the environmental framework in the United States and are emulated in many other countries. Examples of such laws include the Safe Drinking Water Act, and the Clean Air Act. A strong science base is normally required for setting standards, and a science-based risk assessment process undertaken to inform risk management policies and strategies, which of necessity also take into account social, economic, and political considerations.

Policies may also span the spectre of government—from global to local. In general they tend to become more specific and targeted as they go from national to state/provincial/regional to local. In the United States, for example, federal statutes and regulations may be issued and states and local governments will issue statutes or ordinances needed to comply with these, or they may develop their own regulations. Policies may be preventive and aim to reduce hazards directly in a prospective manner (e.g. air pollution regulations) or they may be retrospective and require, for example, clean-up of a toxic waste site. Other types of policies may be aimed at awareness raising and education of the public rather than regulatory control (Johnson 2005).

International policy principles have been adopted as well, for example, coming out of UNCED the Precautionary Principle was adopted, which states 'where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation' (Johnson 2005). Another principle adopted was the Polluter Pays Principle—that is, those who cause pollution should pay the price to clean it up. Economic instruments such as pollutant trading systems are also in use which shift the societal cost of pollution to the polluter (Goldman and Torres 2009).

Impacts originating from a multitude of small sectors rather than from one large obvious source such as a major polluting factory, for example, are often more difficult to control. Smaller enterprises usually have fewer resources at their disposal and are more resistant to change, or may be less knowledgeable about standards which may apply, than large-scale industry. In developing countries, fewer controls are generally applied and control technology may be less well developed. In the absence of local standards (which demand relevant epidemiological and exposure data, which may often not be available), international standards are often applied but may not be appropriate (Goldman and Torres 2009) due to the differing prevailing lifestyles, cultures, climate, demographic attributes, institutional and policy framework, level of economic development, and so on, which differ from country to country.

Environmental standards may be risk based (i.e. based on assessments of environmental or health risks) or technology based (i.e. based on the best available technology) or a combination of both (Goldman and Torres 2009). Pollution prevention is key. Increasingly it has been recognized that controlling pollutants

one medium at a time can result in transferring pollutants from one medium to another, for example, from air to water to land. Multimedia approaches are thus preferable. Reduction of pollution at source is optimal, but other strategies include waste minimization, reuse, recycling, emissions control, and, finally, clean-up. Environmental monitoring has an important role to play in evaluating the success or otherwise of the various control measures adopted, and the public may have an important role in advocacy, monitoring, and enforcement of environmental policies.

Financial incentives

As environmental health protection measures inevitably involve costs, cost-benefit analyses may be undertaken to weigh costs and benefits of an action, while cost-effectiveness analyses might be performed to look at alternative solutions to a problem. Attempts may also be made to assess economic inequities in impacts, taking into consideration issues of environmental justice. Economic and fiscal policies can influence the potential for health gains and their distribution in society. Financial incentives can be set up so that they can contribute to a healthier lifestyle and discourage the use of harmful products and substances. When combined with appropriate legislation and health education programmes many of the negative health trends could be retarded or even reversed.

International regulations

When pollutants cross boundaries, or where there are global impacts and concerns, international agreements and standards come into play. In parallel with the role that international conferences have played in galvanizing action on health and environment issues, so too do international environmental treaties offer the prospect of further advances in public health. Due in part to the WHO's and others' increasing involvement in international conferences and treaty-making processes in recent years, health issues have received increasing recognition and attention. Mechanisms in international environmental law can be used to provide motivations for research aimed at further strengthening the evidence base related to health, and to achieve improved surveillance and monitoring systems concerned with ill health. Increased efforts are needed to more fully realize the potential of international law to promote global environmental health (von Schirnding et al. 2002).

Many multilateral environmental agreements have health implications, for example, the Montreal Protocol on Protection of the Ozone Layer (1987), the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal (1989), the Convention on Biological Diversity adopted in 1992 (including the Cartagena Protocol on Biosafety), the Kyoto Protocol of the UN Framework on Climate Change (1997), the Rotterdam Convention on the Prior Informed Consent Procedure for Certain Hazardous Chemicals and Pesticides in International Trade (1998), and the Stockholm Convention on Persistent Organic Pollutants (2001).

Environmental agreements in existence today, however, recognize the sovereign right and responsibility of nations to set their own standards. So, for example, the Basel Convention does not cover handling and disposal of wastes within a country, and the Rotterdam Convention does not require prior consent for chemicals manufactured and produced within a country (Goldman and Torres 2009).

Conclusion

This chapter has highlighted a number of key issues relating to the nature and practice of environmental health, which is a complex, dynamic, and evolving multidisciplinary field. It is increasingly evident that environmental health practitioners face numerous challenges in addressing the myriad factors influencing health-and-environment relationships in differing contexts and settings.

The multiplicity and interaction of chemical, physical, and biological risks in the environment, the various media and pathways of exposure, the differing vulnerabilities and susceptibilities of diverse groups, and the changing priorities and capacities for the management of environmental health risks in various parts of the world, all need to be addressed by practitioners of environmental health.

Despite dramatic advances in the recognition and amelioration of environmental health risks worldwide in recent decades, there nevertheless remain significant gaps in knowledge of new and emerging risks, and in approaches needed to more effectively address them. Improved indicators which are reflective of complex health-and-environment interactions, and health impact and risk assessment procedures which can better predict impacts associated with differing environment and development parameters and scenarios, are needed.

So too are systems approaches needed for addressing the complexity of issues associated with ecosystems, global change, urbanization, and sectors like energy, housing, and transport. Economic development, the environment, and human health are closely intertwined and interconnected, and need to be addressed as such.

As evidenced by the intersectoral health and sustainable development planning processes which have been underway in recent years at all levels—global to local—there will be more of a need for practitioners to work proactively with communities and other stakeholders and partners in addressing the complexity of health and environment issues. While increasing capacity is needed to assess and address intersectoral impacts, the causes of which frequently lie outside the domain of the health sector, tools like health impact assessment can help to institutionalize intersectoral processes in policymaking and decision-making.

With the continuing development of improved risk assessment procedures and environmental health management tools and policy instruments, and ongoing capacity development of environmental health practitioners and professionals in various settings and tiers of government worldwide, excellence in the practice of environmental health will culminate in increasingly healthier environments for current and future generations to come.

Strategies and structures for public health intervention

Sian Griffiths

Introduction to strategies and structures for public health intervention

The mantra that public health is everybody's business can be two edged. On the one hand, it implies wide support for interventions which would improve health. On the other, it implies such wide responsibility that no one makes public health interventions their priority. Thus, strategies for improving public health and structures for their implementation are complex and situation dependent. It is not always possible to translate a successful programme in city A to one in city B, country C to country D, or urban area E to rural area F. However, the knowledge base for effective interventions is growing and the appreciation of the critical role of cross-sectoral and multilevel approaches is deepening.

In 2012, the American Heart Association published its report on effective interventions with the strongest evidence for improving dietary habits, increasing physical activity, and reducing smoking. Economic incentives to make healthier foods more affordable; improved sidewalk, street, and land-use design to encourage physical activity; and smoking bans were among the 43 most effective interventions identified (American Heart Association 2012).

Thus, public health interventions require a wide range of strategies to translate policies into effective action plans (Kickbusch and Buckett 2010) and structures for their implementation if they are to be effective at producing population-level improvements in health. Strategies may be global agreements, national plans, or local government or community agreements for action. To be implemented, they require structures which are both directly and indirectly concerned with health outcomes, evidence-based processes, and outcome measures of their effectiveness. Strategies may directly involve the health services which make contributions both to improving health, as well as to managing disease, but more often than not, strategies are multisectoral, address the broader determinants of health, and involve an ecological perspective which engages politicians, the corporate sector, civil society, local communities, and the public. This chapter will discuss the concept of strategic approaches for improving the public's health and give examples of health-promoting strategies at global, national, local, and individual levels.

Why a strategic approach?

Health is created by a complex variety of interacting influences. The World Health Organization's (WHO's) definition of health

highlights not only the physical and psychological aspects of good health, but also its socioeconomic and environmental dimensions (WHO 1948). The growing awareness of this broader perspective is currently reflected at many levels, for example, in the growing popularity of the discipline of global health in universities across the United States (Merson and Page 2009), in the emphasis by public health leaders in China on the need for a new curriculum with a biopsychosocial basis for training future public health specialists (Li et al. 2011), and by the repositioning of the public health workforce in England from the health service to work within local governments (Department of Health 2011a).

Increasing awareness of the influence of work on health (WHO Regional Office for the Western Pacific 1999) and the need for positive strategies to promote productivity (Department for Work and Pensions 2008), as well as of the links between education of women (United Nations Population Fund n.d.) and healthier birth outcomes (*The Lancet* 2013a), are further examples, as is the need to respond to the increasing numbers of food scares and scandals (Dai and Jiang 2013), the challenges of food security (WHO n.d. a), and to the growing concerns about the impact of climate change on health (*The Lancet* 2010). Strategies and structures are therefore continually evolving in attempts to meet the impact of these and other changing influences on the public's health.

Strategic development is dynamic and linked to policy. For example, in China, amongst the first challenges faced by the new People's Republic of China in 1949 was the need to improve the general health and hygiene of the population. Strategies for tackling inadequate sanitation, communicable diseases, and providing basic care at the community level for mothers and children led to the creation of the 'barefoot doctor system', a forerunner for many current models of community-based primary care. In the latter part of the twentieth century, China became one of the largest forces in the world economy but during the 'opening up', the lack of strategy for the health services meant that market forces dominated, resulting in greater inequity in health and decimation of the public health system. Health was not a priority and economic strategies held sway. As a consequence, the first decade of the twenty-first century brought the urgent need to bridge the gap between China's world-class economy and its poor health service provision in which many people were unable to afford basic care. The inequities between the affluent East Coast and urban areas were growing and China now faces not only the problems of an increasingly ageing population and

growing challenge from non-communicable diseases (NCDs), but the poorer, less-developed parts of the country remain in greater need of infectious disease surveillance, improvements in maternal health, and implementation of basic primary care programmes, whilst at the same time also facing a growing burden of NCDs. The massive movements of migrants from rural to urban communities, estimated to be around 200 million in 2012, add extra challenges for public health (Jin et al. 2013). At the national level, in addition to hospital service reform, new policies placing greater emphasis on prevention, a stronger public health system, and new strategies to improve primary care are in development to reduce the growing health burdens resulting from rapid urbanization, growing consumption of tobacco, and the increasing rates of lifestyle-related NCDs (The NCD Alliance 2013a).

The experience of China demonstrates the need for national strategy to be interpreted at local levels according to the needs of the population and the resources available. The wide variations in health status, as well as access to care, underline that the delivery of strategy relies not only on national strategic intent, but on appropriate infrastructures and resources at the local level. This was demonstrated in 2003 by the severe acute respiratory syndrome (SARS) epidemic in Hong Kong.

The need for strategy: lessons from SARS in Hong Kong

Amongst the global lessons learned from the experience of SARS in 2003 was that better strategies and structures were needed across all sectors of the health and political systems to respond to the threat of new emerging infectious diseases and to the possibility of a pandemic. When SARS hit Hong Kong in 2003, its surveillance systems were focused on the possibility of an H5N1 (avian flu) pandemic and influenza-like illnesses, and were monitoring in the hospital system. Activity on the Hong Kong borders, where shop shelves were emptied of white vinegar to be boiled by local residents as protection from a serious unknown disease, was not detected and there was no formal accurate information about the atypical pneumonia outbreak in the Guangdong Province available to Hong Kong or to the international community at the time. Only when a group of healthcare workers and medical students in Hong Kong were admitted to one of the largest teaching hospitals within a few days in early March with an unidentified respiratory illness was alarm triggered in the healthcare community.

Whilst the story of the spread of the disease to the local community and to the rest of the world is now well known, the Independent Inquiry commissioned by the Hong Kong government (Hong Kong Special Administrative Region Government 2003) provided the opportunity to review what strategies had been in place and how well they had worked. The Inquiry found that whilst the healthcare staff could be commended for the care they gave the patients, the healthcare system itself had structural deficits and the strategy for action was inadequate. The ability to rapidly legislate to designate the new disease as notifiable was not in place, and interventions were hindered by outdated legislation. The organization of health protection functions, hospital management, and the relationships with central government all needed review. Better collaboration and communication outside Hong Kong, within Hong Kong, and within the healthcare sector was also needed, and it was recognized that to manage workforce capacity for future epidemics, training and research were all

needed. These findings had much in common with the Canadian experience (the country hardest hit by SARS outside of Asia), where it was found that amid the commendable response by public health and healthcare workers to contain SARS, there were still many systematic deficiencies to adequately address outbreak containment, surveillance, information management, and infection control (Naylor et al. 2004).

Since 2003, policy changes in both jurisdictions amongst others, including China, Canada, and Singapore, have resulted in significant progress in strengthening their structures and strategies to combat emerging infectious diseases. In Hong Kong, as in many other countries, surveillance information is now available through a real-time system of reporting of data not only across the Pearl River Delta but globally through the network coordinated by the WHO. Active networks not only of government officials responsible for resilience, but also of researchers, are in regular communication. Communication between the hospital and the community has been improved by streamlined systems and the creation of geographical coterminosity between catchment areas. Extensive plans are now in place for all sectors and staff to be trained through ‘drills’ which are intersectoral, and which have clear leadership and chains of command and control. The public and the media are better informed about communicable diseases and about preventive measures, such as hand washing. Efforts are continually being made to ensure that communication is open and transparent with press releases and letters to medical staff to keep them abreast of emergent diseases.

The new improved infrastructure was put to the test in 2008 with the threat of the H1N1 pandemic (Cowling 2010). Unlike the SARS experience of 2003, the media and politicians worked together to ensure public health messages about H1N1 were clear and well communicated to the public, based on up-to-date information regularly provided by the Centre for Health Protection (CHP). The CHP, which was established post SARS, was able to play its part in the global network of surveillance for communicable diseases acting as the central structure to coordinate local responses, and ensuring global collaboration and communication (Hong Kong Government n.d.).

The experiences of SARS and H1N1, and more recently H7N9 in Asia and the Middle East respiratory syndrome coronavirus (MERS-CoV), have demonstrated the need for cross-sectoral strategy, a clear plan for proposed implementation, as well as identified structures to support its implementation. The experience of H1N1 demonstrated that both strategy and structures had improved with the lessons learned from SARS and, in 2013, the flow of information about H7N9 to the press, various professions, and the public is significantly better, as is the support from the global scientific community.

Defining strategy

Strategies are, therefore, a necessary step in the translation of policies into plans and action. They create the bridge between policy and practice. Mintzberg (1987) has described five aspects of strategies:

1. Plan—with purposeful intended action.
2. Ploy—competitive manoeuvring.
3. Pattern—signalling a plan in a series of actions.

4. Position—relevant to the outside world.
5. Perspective—an organizational personality.

Translating the aspects of strategy into public health practice requires certain features:

1. Focus on populations rather than individuals.
2. Address the social determinants of health and their impact on poverty.
3. Be based on values of social justice and equity.
4. Reflect a global perspective.
5. Be aware of the dynamic relationship between the environment and health.
6. Place priority on prevention rather than curative care.
7. Understand the importance of systems and structures.
8. Take a transdisciplinary and multisectoral approach.
9. Ensure decision making is based on:
 - a. vital statistics (population-based data)
 - b. data, scientific evidence, and good research
 - c. surveillance and outbreak investigation.
10. Be committed to advocacy and in tune with politics.

Strategic plans may relate to the health status or needs of a defined group of people or of the population as a whole, and may take various forms, such as laws, rules and regulations, guidelines, recommendations, and mandates (Kawamoto 2004).

Health strategy and health service strategy are both important for delivering better public health interventions. Health services are responsible for dealing with disease, and they do not control the major forces which cause disease. They can, however, play a significant role in prevention both at institutional and individual levels through the services they provide and the institutional influences they exert. Health strategy is, however, conceptually broader and requires engagement at different population levels with a wide variety of forces which impact on health—social, economic, political—and with a wide range of multisectoral stakeholders. Strategies for health are underpinned by values, such as those supporting the Millennium Development Goals (MDGs), a strategy to eliminate world poverty (UN n.d. a, n.d. b), which is based on the unacceptability of poverty and disadvantage, and committed to promoting equity and greater opportunity for the 20.6 per cent of the world's population still living on less than \$US1.25 a day. Improving public health is a key component of the MDGs—both directly, in the aspirations to improve child health and maternal health and to combat HIV/AIDS, and also indirectly through strategies for raising educational standards, promoting gender equality, and seeking environmental sustainability—all of which will improve the health of populations.

The 2010 MDG Summit concluded with the adoption of a global action plan, 'Keeping the Promise: United to Achieve the Millennium Development Goals', and the announcement of a number of initiatives against poverty, hunger, and disease. In a major push to accelerate progress on women's and children's health, a number of heads of states and governments from developed and developing countries, along with the private sector, foundations, international organizations, civil society, and

research organizations, pledged over \$40 billion in resources over the next 5 years (UN n.d. b).

As the timeline for achievement of the MDGs approaches, the next phase of the post-2015 agenda is being considered, with many advocating for issues such as a greater focus on both overnutrition with its impacts on the increasing burden of NCDs and also on undernutrition.

'For mothers, this means less strength and energy for the vitally important activities of daily life. It also means increased risk of death or giving birth to a pre-term, underweight, or malnourished infant. For young children, poor nutrition in the early years often means irreversible damage to bodies and minds during the time when both are developing rapidly. And for 2.6 million children each year, hunger kills, with malnutrition leading to death' (Save the Children 2012).

Undernutrition is the single greatest cause of child deaths in most low- and middle-income countries (World Bank 2013) with the most effective preventive public health strategies including promoting breastfeeding, supplementing diets with micronutrients, immunization, and hygiene.

Levels of health strategy: global, national, local, and individual

Overview

Strategies may be at multiple population levels and be influenced not only by local factors, but also by global policies, linking both vertically and horizontally. Vertical strategies may be concerned with single programmes, such as those addressing HIV/AIDS in sub-Saharan Africa, whereas horizontal strategies may focus on addressing a wider range of influences such as those creating or alleviating poverty.

Poverty and poor health are inextricably linked and strategies to reduce poverty are essential for improving health opportunity. Addressing the root causes of poverty whilst promoting greater equity are key strategic objectives underpinning the work of the WHO Commission on Social Determinants of Health (2008), an influential global think tank which has raised the profile of the debate on the need for strategic action across four main dimensions—political, economic, social, and cultural.

Health is a universal aspiration and a basic human need. The development of society, rich or poor, can be judged by the quality of its population's health, how fairly distributed across the social spectrum and the degree of protection provided from disadvantage due to ill-health. Health equity is central to this premise. (Commission on Social Determinants of Health 2008, p. 7)

Proposed strategies to reduce health inequity include:

1. Improving the conditions of daily life at home and at work, for women and men, in rural and urban settings, and for all ages.
2. Addressing the inequitable distribution of power and money, forces that shape the conditions of daily life.
3. Acting based on knowledge, a professional workforce, alliances with civil society, and evaluation.

The Commission did not stop with making these strategic statements, but has backed them up with a series of papers which provide examples of good practice to support their implementation.

The work of the Commission can be contextualized within a framework of strategic declarations from the WHO, particularly from the Declaration of Alma Ata (WHO 1978). This declaration, and subsequent iterations, echo public health's historic roots by reflecting the importance of the socio-environmental conditions in which people live and the need for community-based action to improve health. Emphasis is placed on the importance of interactive roles of government, communities, and individuals alongside the healthcare sector to promote good health and prevent disease. Whilst the health sector has a role in promoting health through the services it provides, its role beyond acute medical care is significant with potential for involvement with upstream activity to prevent ill health in the entire population. This was proposed in the Declaration of Alma Ata, which called for 'a comprehensive health strategy that not only provided health services but also addressed the underlying social economic and political causes of poor health'. De facto effective prevention would rely on working with, and across, other sectors and, in particular, promoting joined-up government at all its levels including greater community engagement through better primary care.

The conceptual framework of Alma Ata was further developed by the Ottawa Charter (WHO 1986), which promoted the concept of healthy public policy rather than focusing only on health policy, extending consideration of health to all policy environments, including the concept of health impact assessment.

The *Ottawa Charter* defined five key areas for strategic public health action:

1. Building healthy public policy.
2. Creating supportive environments.
3. Strengthening community action.
4. Developing personal skills.
5. Reorienting health services towards prevention and a holistic approach (WHO 1986).

The Ottawa Charter stated unequivocally that health is created in the context of everyday life where people live, love, work, and play. It expanded the concept of health determinants to include environmental challenges and people's empowerment. It included not only the basic well-described determinants but broadened the strategic thinking to the need to combine diverse but complementary approaches in order to promote lifestyles conducive to health. These now include, in particular, legislation, fiscal measures, taxation, and organizational change.

Subsequently, in 2005, the *Bangkok Charter* (WHO 2005) further broadened the notion of 'Health in All Policies' (HiAP) by highlighting the need to work across the corporate sector and at a global level, stating that the promotion of health was:

1. Central to the global development agenda.
2. A core responsibility for all governments.
3. A key focus of communities and civil society.
4. A requirement for good corporate practice.

Underpinning concepts included those of social justice, stressing the importance of the values of gender and health equity, respect for diversity and human dignity, and the search for peace and security.

A further iteration has been the move to ensure HiAP (European Portal for Action on Health Inequalities n.d.) and to develop public health policy from the starting point of the crucial role that health plays in the economic life of a society. The central concern of this approach is that the health impacts of policy affect all sectors, and thus governments should adopt a systematic approach to addressing the key determinants of health by considering the impact on health of all their policies. Better health is both a fundamental human right and a sound social investment. Thus within healthy public policy, there needs to be an explicit concern for health and equity in all areas of policy and an accountability for the health impact of these policies. The development of healthy public policy requires not only an investment of resources by government—linking economic, social, and health policies—but also a foundation built on the basic principles of social justice to ensure health promotion and healthy lives. In their review of HiAP, Leppo et al. stress that, in practice, it is usually also necessary to prioritize efforts and to seek synergies to enhance health and other important societal goals (Leppo et al. 2013). HiAP stresses a whole of government approach. As demonstrated by the Pan American Health Organization (PAHO) series of case studies (Etienne et al. 2013), working together and across sectors is not only more effective, but also a prerequisite to further improve the health and well-being of communities at the national, regional, and global level. In selecting the case studies the PAHO team used the criteria that the project included demonstration of political support at a high level, had formal intersectoral structures and a specific budget with explicit commitment from other sectors if they were to be included as part of this initiative, and that the project would reduce health inequity. Scientific evidence of the impact of the programme and mechanisms for participation and community empowerment were also essential.

The implementation of the HiAP approach relies on resources and skills, good information, and a supportive context with political will and governance structures and processes for intersectoral communication and implementation (Pitcher et al. 2010).

Example of HiAP: South Australia's Strategic Plan

Adopting the HiAP's approach, South Australia's Strategic Plan (SASP) expresses the values, priorities, and actions for the future direction of the state. It provides a reference point for the activities of the government through each of its agencies, and describes a whole-of-state plan with 98 targets that can be achieved only through cooperation within and between government, industry, and the community. Its objectives are to:

- ◆ Grow prosperity.
- ◆ Improve well-being (which contains a number of health-specific targets).
- ◆ Attain sustainability.
- ◆ Foster creativity and innovation.
- ◆ Build communities.
- ◆ Expand opportunity.

An important feature of SASP is that neither the objectives nor any individual targets stand alone—they are all part of a larger, interrelated framework and achieving one does not come at the expense of another. The aim is to encourage collaborative

behaviour and innovative thinking to address some of the most complex issues facing Southern Australia (Pitcher et al. 2010).

HiAP has also been adopted by the European Union (EU) as part of its strategic approach seeking to complement national action on health. The EU health policies aim to:

- ◆ Protect people from health threats and disease.
- ◆ Promote healthy lifestyles.
- ◆ Help national authorities in the EU cooperate on health issues (European Commission 2007).

HiAP is one of the four principles adopted by the EU. The three further principles are:

- ◆ *A strategy based on shared health values:* this principle places particular emphasis on reducing poverty and inequities and on the importance of indicators of comparable health data at all levels. Further work on how to reduce inequities in health and how to promote health literacy programmes for different age groups is part of the strategic approach.
- ◆ *Health is the greatest wealth:* highlights that spending on health is not just a cost, it is an investment and that although health expenditure may be regarded as an economic burden, the real costs to society are the direct and indirect costs linked to ill health. The report estimates that the annual economic burden of coronary heart disease can amount to 1 per cent of the gross domestic product (GDP), and the costs of mental disorders to 3–4 per cent of the GDP. It emphasizes that with 97 per cent of spending going on acute care healthcare and treatment, there is an underinvestment in prevention and improving of the population's overall physical and mental health.
- ◆ *Strengthening the EU's voice in global health:* the EU's contribution to global health requires interaction of policy areas, such as health, development cooperation, external action, research, and trade linking with the WHO and other relevant United Nations (UN) agencies, the World Bank, the International Labour Organization, the Organisation for Economic Cooperation (OECD), and the Council of Europe, as well as other strategic partners and countries.

The strategy has three objectives related to its policy priorities, which together culminate in an overarching framework for action at all levels across the population:

1. *Fostering good health in an ageing Europe:* promoting health and preventing disease requires efforts throughout the lifespan to tackle key issues including poor nutrition; physical activity; alcohol, drugs, and tobacco consumption; environmental risks; traffic accidents; and accidents in the home. Improving the health of children, adults of working age, and older people will help create a healthy, productive population and support healthy ageing now and in the future.
2. *Protecting citizens from health threats:* emphasizing the need for surveillance and mechanisms to respond to health threats, including emerging infections, as well as adaptation to climate change.
3. *Supporting dynamic health systems and new technologies:* e-health, genomics, and biotechnologies can improve prevention of illness, delivery of treatment, and support a shift from hospital care to prevention and primary care. New technologies

must be evaluated properly, including for cost-effectiveness and equity, and health professionals' training and capacity implications must be considered.

The EU health strategy creates a framework within which jurisdictions take forward their own strategies tailored to national needs. It raises not only the aspirations but also the need for effective implementation and for monitoring progress.

Another example of a continent-wide strategy addressing different health needs comes from Africa where significant numbers of low-income countries face different challenges associated with poverty and infectious diseases. The strategy produced by the African Union Ministers of Health is structured using the framework of *Vision and Mission, Principles, Goals, and Objectives*.

Its goal is to contribute to Africa's socioeconomic development by improving the health of its people and by ensuring access to essential healthcare for all Africans, especially the poorest and most marginalized, by 2015. The vision is expressed as working towards 'an integrated and prosperous Africa free of its heavy burden of disease, disability and premature death', and the mission is to build an effective, African-driven response to reduce the burden of disease and disability through strengthened health systems, scaled-up health interventions, intersectoral action, and empowered communities. The strategic principles include health as a human right and a developmental concern requiring a multisectoral response, equity in healthcare as a foundation for all health systems, and effectiveness and efficiency as central to realizing the maximum benefits from available resources. Evidence is proposed as the basis for sound public health policy and practice and more of the same is not enough: 'new initiatives will endeavour to set standards that go beyond those set previously' (NEPAD n.d.).

Global-level action

Whilst the previous examples have been concerned with strategic aspirations for their own geographical location, other strategies focus more globally. For example, the US Centers for Disease Control and Prevention's (CDC's) Global Health Strategy 2012–2015 (CDC 2012) outlines how the CDC will leverage its core strengths to advance four overarching global health goals: improving the health and well-being of people around the world, improving capabilities for preparing and responding to infectious diseases and emerging health threats, building country public health capacity, and maximizing organizational capacity. The US Department of Health and Human Services (HHS) has also produced a Global Health Strategy based on the underlying principles of:

- ◆ Using evidence-based knowledge to inform decisions.
- ◆ Leveraging strengths through partnership and coordination.
- ◆ Responding to local needs.
- ◆ Building local capacities.
- ◆ Ensuring a lasting, measurable impact.
- ◆ Emphasizing prevention.
- ◆ Improving the equity of health.

Three fundamental goals and ten key objectives contribute to achieving HHS's global health vision of a healthier, safer world.

This strategy is another example of the acceptance of the important links between health, politics, and economics, as well as of health and security with broad objectives, such as leadership and technical expertise in science; policy, programmes, and practice to improve global health; advancing US interests in international diplomacy; development and security through global health action; and increasing the safety and integrity of global manufacturing and supply chains and advancing health diplomacy (United States Global Health n.d.).

Whilst the HHS strategy for global health demonstrates the importance of the global conditions needed to generate health, other strategies will focus on diseases, conditions, age groups, or predeterminants. Strategies may be produced by governments at a local or national level, by interest groups or NGOs, or by other institutions with an interest in health. For example, governments in Australia, Canada, and the United Kingdom, as well as others, are producing strategies for mental health. The aims of the Australian national mental health strategy, for instance, are to:

- ◆ Promote the mental health of the Australian community.
- ◆ Where possible, prevent the development of mental disorders.
- ◆ Reduce the impact of mental disorders on individuals, families, and the community.
- ◆ Assure the rights of people with mental illness.

Produced in 2002, it remains under constant revision and includes the:

- ◆ National mental health policy.
- ◆ National mental health plan.
- ◆ Mental health statement of rights and responsibilities (Australian Government Department of Health and Ageing 2012).

Changing Directions, Changing Lives is the first Canadian mental health strategy and was published in 2012. The strategy was produced 'to help to ensure that people who experience mental health problems and illnesses—especially those with the most severe and complex ones—are treated with respect and dignity, and enjoy the

same rights as all Canadians'. The strategy provides six strategic directions for change to improve mental healthcare (Box 11.6.1).

Change will not be possible without a whole-of-government approach to mental health policy (Mental Health Commission of Canada 2012).

In England, the mental health strategy published in 2011 follows many of the same themes. *No Health Without Mental Health: A Cross-Government Mental Health Outcomes Strategy for People of All Ages* sets shared objectives to improve people's mental health and well-being, and plans to improve services for people with mental health problems. The strategy sets out the policy for how the government, working with all sectors of the community and taking a life course approach, will improve the mental health and well-being of the population and provide people with high-quality services that are equally accessible to all (Department of Health 2011b).

The strategy incorporates the key elements of defining a policy, setting out aims and objectives, and proposing goals and how they will be monitored. The key elements of the English national policy are expressed as:

Putting people who use services at the heart of everything we do: 'No decision about me without me' is the governing principle. Care should be personalized to reflect people's needs, not those of the profession or the system. People should have access to the information and support they need to exercise choice of provider and treatment; focusing on measurable outcomes and the NICE Quality Standards that deliver them rather than top-down process targets; and empowering local organizations and practitioners to have the freedom to innovate and to drive improvements in services that deliver support of the highest quality for people of all ages, and all backgrounds and cultures. (HM Government 2011)

Strategies may also be focused on specific diseases, for example, NCDs. Globally, the overall economic and social costs of NCDs are vastly in excess of their direct medical costs. In addition to their burden on health systems, NCDs impact on economies, households and individuals, and result in poverty, inequity, and opportunity loss. The burden of NCDs continues to grow not only in affluent countries, but in low- and middle-income countries as

Box 11.6.1 Six strategic directions for changes to improve mental health and the mental health care system

1. To promote mental health across the lifespan in homes, schools, and workplaces, and prevent mental illness and suicide wherever possible.
2. To foster recovery and wellbeing for people of all ages living with mental health problems and illnesses, and uphold their rights.
3. To provide access to the right combination of services, treatments and supports, when and where people need them. A full range of services, treatments and supports includes primary health care, community-based and specialized mental health services, peer support, and supported housing, education and employment.
4. To reduce disparities in risk factors and access to mental health services, and strengthen the response to the needs of diverse communities and Northerners.
5. To work with First Nations, Inuit, and Métis to address their mental health needs, acknowledging their distinct circumstances, rights, and cultures.
6. To mobilize leadership, improve knowledge, and foster collaboration at all levels.

well, where 80 per cent of NCD deaths occur (Mohammed n.d.). For example, in China, reducing cardiovascular mortality by 1 per cent per year between 2010 and 2040 could generate an economic value equivalent of 68 per cent of China's real GDP in 2010 or over US\$10.7 trillion (World Bank 2011). In Egypt, NCDs could be leading to an overall production loss of 12 per cent of Egypt's GDP (Rocco et al. 2011) and, in Brazil, the cost of NCDs between 2005 and 2009 was predicted to equal 10 per cent of Brazil's 2003 GDP (World Bank 2005). In India, eliminating NCDs could have, in theory, increased India's 2004 GDP by 4–10 per cent (Mahal et al. 2009).

Thus, NCDs are a long-standing, progressive, and costly threat to healthy populations. Diseases such as diabetes are associated not only with the problems of diminished functional capacity, increased physical and psychosocial morbidity, co-morbidities, and complications, but also lead to higher utilization of health services and higher medical costs, as well as opportunity costs that are associated with self-care and disability and shorter life expectancy than those without diabetes.

The global concern with NCDs is reflected by their strategic priority on the agenda not only of the WHO, but also of the UN. In 2011, the Secretary General of the UN, Ban Ki-Moon, in remarks to the General Assembly meeting on the Prevention and Control of Non-Communicable Diseases, stated that 'addressing NCDs is critical for global public health, but it will also be good for the economy, for the environment, for the global public good in the broadest sense. If we come together to tackle NCDs, we can do more than heal individuals—we can safeguard our very future' (UN News Centre 2011).

Senior scientists and clinical academics have also added their voices, for example, in the grand challenges to address the threat by:

- ◆ Raising public awareness.
- ◆ Enhancing economic, legal, and environmental policies.
- ◆ Modifying risk factors.
- ◆ Engaging businesses and the community.
- ◆ Mitigating health impacts of poverty and urbanization.
- ◆ Reorienting health systems (Daar et al. 2007).

The WHO continues to build on the Global Strategy for the Prevention and Control of NCDs (WHO 2013a), which was first adopted in 2000, and has been followed by strategies to address tobacco control, and lifestyle factors such as diet, exercise, and alcohol consumption. These have so far materialized into the Physical Activity and Health campaign (WHO 2004), the Reduction of Harmful Use of Alcohol campaign (WHO n.d. b), as well as an Action Plan for the Global Strategy for the Prevention and Control of NCDs for 2008–2013 (WHO 2009a). This set of actions also called for high-level political commitment and the concerted involvement of governments, communities, and health-care providers for successful implementation. The 66th World Health Assembly (WHA) in 2013 concluded with Member States adopting an 'omnibus resolution' on NCDs. This resolution combined major decisions and recommendations in a single, comprehensive resolution, including:

- ◆ Adopting the global monitoring framework (GMF), including nine targets and 25 indicators.

- ◆ Endorsing the Global NCD Action Plan 2013–2020 (GAP).
- ◆ Agreeing to establish a global coordination mechanism (GCM) for NCDs, and to develop terms of reference by November 2013.
- ◆ Agreeing to establish a set of indicators to measure the implementation of the GAP (The NCD Alliance 2013b).

The GAP lays out the vision of a world free of the avoidable burden of NCDs with the goal of reducing the preventable and avoidable burden of morbidity, mortality, and disability due to non-communicable diseases. The means of achievement will be through multisectoral collaboration and cooperation at national, regional, and global levels. The objective is for populations to reach the highest attainable standards of health and productivity at every age so that NCDs are no longer a barrier to well-being or socioeconomic development (WHO 2013b).

The principles adopted should be:

- ◆ 'Life-course approach
- ◆ Empowerment of people and communities
- ◆ Evidence-based strategies
- ◆ Universal health coverage
- ◆ Management of real, perceived or potential conflicts of interest
- ◆ Human rights approach
- ◆ Equity-based approach
- ◆ National action and international cooperation and solidarity
- ◆ Multisectoral action.' (WHO 2013b)

The objectives of the plan are to raise the priority given to the prevention and control of NCDs at all levels, through strengthened international cooperation and advocacy; to strengthen national capacity, leadership, governance, multisectoral action, and partnerships to reduce modifiable risk factors and underlying social determinants through creation of health-promoting environments; and to strengthen and orient health systems to people-centred primary healthcare and universal health coverage. This should be underpinned by promoting and supporting national capacity for high-quality research and development as well as monitoring the trends and determinants of NCDs to evaluate progress in their prevention and control.

Progress can be measured by adopting voluntary global targets (Box 11.6.2).

By creating a framework and setting targets, emphasis is shifting from analysis of the problem to implementing changes that can make a difference, monitored through a set of measurable outcomes.

National-level action

Whilst at a *global level* the WHO produces strategies to provide direction for change, action to implement change is needed at a national population level. Examples of national strategies for mental health were given earlier in this chapter—each being country specific. Another approach is the proposal for a common framework for national action, an example of which is the Framework Convention on Tobacco Control (FCTC) (WHO n.d. c), which was the first international treaty negotiated under the auspices of the WHO, adopted by the WHA on 21 May 2003 and entered into force on 27 February 2005. It was developed in response to the threats posed by the globalization of the tobacco epidemic and is an evidence-based treaty that reaffirms the right of all people to the highest standard of health. By mid 2013, 176 jurisdictions had signed up to the Convention, including 90 per cent of the world's population.

Box 11.6.2 Voluntary global targets

1. A 25 per cent relative reduction in risk of premature mortality from cardiovascular diseases, cancer, diabetes, or chronic respiratory diseases.
2. At least 10 per cent relative reduction in the harmful use of alcohol, as appropriate, within the national context.
3. A 10 per cent relative reduction in prevalence of insufficient physical activity.
4. A 30 per cent relative reduction in mean population intake of salt/sodium.
5. A 30 per cent relative reduction in prevalence of current tobacco use in persons aged 15+ years.
6. A 25 per cent relative reduction in the prevalence of raised blood pressure or contain the prevalence of raised blood pressure, according to national circumstances.
7. Halt the rise in diabetes and obesity.
8. At least 50 per cent of eligible people receive drug therapy and counselling (including glycaemic control) to prevent heart attacks and strokes.
9. An 80 per cent availability of the affordable basic technologies and essential medicines, including generics, required to treat major noncommunicable diseases in both public and private facilities.

Support for *national-level* implementation has been provided by the *WHO MPOWER package* (WHO n.d. d), which gives strategic advice on six proven evidence-based policies to reduce tobacco-related harm (see also Chapter 9.1). This is a vertical strategic approach, focusing specifically on one risk factor, tobacco smoking. The recommended headline actions are:

- Monitor tobacco use and prevention policies
- Protect people from tobacco smoke
- Offer help to quit tobacco use
- Warn about the dangers of tobacco
- Enforce bans on tobacco advertising, promotion, and sponsorship
- Raise taxes on tobacco. (WHO n.d. d)

Importantly, MPOWER provides examples of successful initiatives which have reduced the burden of tobacco-related harm. For example, legislation is a key element to achieving the MPOWER measures and many countries have actively legislated to stop smoking in public places through the banning of tobacco smoking indoors in environments such as workplaces, shops, restaurants, bars, and residential care homes. In 2013, additional steps have been taken in Australia to introduce plain packaging of cigarettes and are now being studied by other countries who are deciding whether to follow suit (*The Lancet* 2013b).

But, whilst national legislation can provide environments in which tobacco harm is reduced, local strategies are also necessary particularly to engage the health sector.

Local-level action

Engagement of health services at a *local level* has been shown to be essential for the translation of the objectives of the FCTC. Whilst health promotion in schools about the harms of tobacco in schools plays an important role in raising awareness, local services also need to provide support such as smoking cessation services in special clinics and within routine services in both public and private sectors. Non-government organizations (NGOs), for example, the

Action on Smoking and Health (ASH) in the United Kingdom (ASH UK n.d.) and Australia (ASH Australia n.d.), and the Hong Kong Council on Smoking and Health (COSH) (n.d.) provide invaluable support in both leading and assisting the implementation of strategies. In Hong Kong, COSH advocates with government and also provides additional services and support for smokers who wish to quit, such as manning quitlines, organizing local campaigns, and providing smoking cessation information. Smoking cessation community clinics, such as the Hong Kong's Hospital Authorities' Smoking Cessation and Counselling Centres, are supported by other NGOs, as well as the government, and increase the effectiveness of smoking cessation services by providing nicotine replacement therapy and continuity of care. Among smokers who are aware of the dangers of tobacco, three out of four want to quit. Like people dependent on any addictive drug, it is difficult for most tobacco users to quit on their own, and they benefit from help and support to overcome their dependence from a variety of sources including local clinics, support groups, and advice from helplines.

Whilst MPOWER seeks to provide global guidance that can be translated into local action, other strategies will be jurisdiction specific. Typically such strategies describe the epidemiology of the target population, its demography, the distribution of mortality and morbidity, its health needs, and local characteristics. Since the purpose of a strategy is to bring about change, plans for implementation will be included, as well as a framework for monitoring and evaluation, often promoting targets or objectives to be achieved. Many countries have produced strategies for tackling major health priorities, including strategies for addressing the epidemic of NCDs.

Typically, development of a strategic framework at a *local level* will analyse needs, priorities, and plans for implementation of a policy and engage stakeholders in its implementation. One example of this approach comes from Hong Kong where, in line with

WHO and the Western Pacific Regional Action Plan (WPRO) NCD strategies, the Hong Kong Department of Health has developed a strategic framework for NCDs (Hong Kong Government 2013). This framework was produced following a series of processes engaging not only with the health sector but more widely, particularly with the NGO sector which plays a significant role in health promotion and service delivery.

The first step was to review international literature as well as local epidemiology and health service information. The plan was then drawn up using a set of strategic principles (Box 11.6.3).

To flesh out the framework, the strategy group engaged other arms of government, professional groups, non-government agencies, representatives of the business sector, and the community to agree on a work programme based on promoting the need for prevention and early intervention, and to ensure that any action was

to be evidence based, outcome focused, and addressing broader health determinants to reduce the burden of disease related to NCDs. Particular emphasis was placed on informing the population to promote responsibility for their own health, engagement of public and private sectors, engaged professionals, and a sustainable health system (Hong Kong Government 2013).

Implementing strategy

With frameworks and principles for strategy in place, action to address specific health behaviours and challenges needs to be planned and monitored. In Hong Kong, for example, a government-level committee to review progress on strategy implementation, chaired by the health minister, was established. Task forces were then established to develop action plans for the four

Box 11.6.3 Principles for strategy development

1. *Viewing health from a public health perspective:* the patterns of NCDs in the whole population were considered.
2. *Understanding health determinants:* taking account of the general socioeconomic and cultural environments and their impact on communities, as well as health behaviours.
3. *Considering health disparity/inequity:* diseases are unfairly distributed and poorer communities have higher rates of disease, seek health services later, and often have less access to healthcare.
4. *Clustering of risk factors in the community:* many NCDs share common behavioural risk factors and many people have more than one chronic disease leading to multi-morbidity. For example, four of the most important NCDs—diseases of the circulatory system, cancer, chronic respiratory diseases, and diabetes mellitus—share three major behavioural risk factors, namely smoking, physical inactivity, and unhealthy diet, and are mediated through common biomedical risk factors, notably excess weight, hypertension, and an adverse lipid profile. Local information about disease patterns, such as mortality from cancer, behaviours such as smoking rates, and hospital admission rates for cardiovascular disease, all helped to provide the scale and distribution of the burden of NCDs in the community.
5. *Adopting the life course approach:* the life course approach acknowledges the interactive and cumulative impact of social and biological influences throughout life, particularly the importance of predisposing factors in early life.
6. *Identifying a preventive strategy:* three levels of prevention are recognized as essential considerations for the strategy: primary, secondary, and tertiary. Primary prevention is concerned with measures that prevent the onset of disease, for example, health education and immunization. Secondary prevention inhibits the progression of a disease after its occurrence by early detection and diagnosis followed by prompt and effective treatment. Screening programmes for cancers or hypertension are examples of secondary prevention. Tertiary prevention refers to the rehabilitation of patients with an established disease with the objective of minimizing residual disabilities and complications, and maximizing potential years of life.
7. *Balancing population-wide versus individual-based approaches:* population-wide approaches seek to achieve an overall lowering of the risk in the whole population. Individual-based approaches identify the high-risk individuals.
8. *Recognizing the importance of health literacy and social marketing:* health literacy (WHO n.d. e) is the ability to read, understand, and act on healthcare information. Poor health status is associated with low health literacy. Social marketing (Lefebvre and Flora 1988) is an approach which focuses on motivating people to use health information and change behaviour in ways that promote and maintain good health. Effective social marketing, which may be promoted by different sectors, such as healthcare providers, local health departments, NGOs, or national government offices use different communication channels like mass media, message placement in clinics, and community-level outreach to influence health behaviour among target populations and audiences (Evans 2006) of varying levels of health literacy and health behaviours.
9. *Setting health priorities:* priority setting is necessary for the rational utilization of resources for public health programmes in a community.
10. *Establishing a framework for monitoring and evaluation.*

Source: data from Hong Kong Government, Department of Health, *Promoting Health in Hong Kong: A Strategic Framework for Prevention and Control of Non-communicable Diseases*, available from http://www.change4health.gov.hk/filemanager/common/image/strategic_framework/promoting_health/promoting_health_e.pdf.

Box 11.6.4 Example of strategy implementation: reducing alcohol harm in Hong Kong

Having identified reducing alcohol harm as a priority for implementing the NCD strategy, the HK Working Group on Injuries and Alcohol Misuse proposed ten recommendations to address alcohol related harm (Hong Kong Government 2011):

1. Strengthen surveillance of alcohol consumption through collecting data from all sectors.
2. Strengthen surveillance of alcohol-related harm by collecting data from the healthcare sector.
3. Promote research to understand drinking patterns, particularly among the young, and assessment of impact of measures taken.
4. Involve all health professionals through education and practice.
5. Encourage healthcare professionals to identify at-risk drinkers and explore the development of tools to enable this to happen.
6. Provide secondary, tertiary, and mental health services for those identified with needs.
7. Working together of government, NGOs, schools, and employers in partnership to maximize efforts.
8. Develop evidence-based and culture-relevant advice and information that can be disseminated in all sectors.
9. Strengthen community awareness and actions through publicity, media, and other means.
10. Review legislation and consider age restrictions for selling alcohol.

The recommendations were then used to establish process measures for monitoring implementation and various partners, such as NGOs and community groups, were involved in promoting the strategy. Healthcare providers were also included to provide health education and care for individuals and to engage with professional groups.

Source: data from Hong Kong Government, Department of Health, *Promoting Health in Hong Kong: A Strategic Framework for Prevention and Control of Non-communicable Diseases*, available from http://www.change4health.gov.hk/filemanager/common/image/strategic_framework/promoting_health/promoting_health_e.pdf.

priority areas: diet, physical activity, alcohol (see Box 11.6.4), and injury. Other established groups developed action plans including those for reducing tobacco smoking, better primary care, and cancer prevention. Cross-referencing and shared initiatives were coordinated through the strategy's steering group.

Action aimed to be population based and outcome focused, and included developing health education materials for educators and healthcare professionals, and developing guidelines for screening and brief interventions to identify and manage at-risk drinkers. Emphasis is placed on increasing an individual's ability to make informed choices about alcohol consumption. It was also important that the steering groups represented their organizations and that the plans were derived with their input and shared with their colleagues, including top management in their institutions.

As in many cases, agreeing on the plan was relatively straightforward, but its implementation has been less so. At a territory-wide level, implementation has been complicated by the aspirations not only of the alcohol industry but also the government itself to promote alcohol sales. When the financial secretary announced a tax reduction for wine and beer, the health sector was caught unawares. This tax reduction was solely for financial reasons—to stimulate the economy and to make Hong Kong a centre for wine trading. The health consequences of cheaper alcohol were not a consideration for this policy change despite the clear evidence from other countries showing that unit price increase for alcoholic drinks is one of the most effective ways to reduce alcohol-related harm, and it is therefore not surprising that early indications are that alcohol sales have dramatically increased (Kim et al. 2013).

This example demonstrates the difficulties often faced by public health interventions in which gaining consensus is easier than implementing the recommendations.

Putting strategy into action at a local level

The process of strategy development uses the whole range of public health tools and skills. Much of the focus of the work will be on the process of gaining commitment from partners, patients, and the public, and overcoming the barriers they perceive. Successful implementation relies on clarity of the health challenge, key aims and objectives, as well as structures which support engaging the right people in the community to create change, and ensure that proposed changes are implemented and sustainable. Some key questions guiding local-level action are shown in Table 11.6.1.

Structures for implementing strategy: the PEOPLE framework:

The acronym PEOPLE (Hong Kong Government 2013, pp. xiii–xiv) can be used as a tool to review the structural support for strategy implementation:

1. Partnership.
2. Environment.
3. Outcome-focused.
4. Population-based interventions.
5. Life course approach.
6. Empowerment.

1. Partnership

Partnerships between different sectors of society and at different population levels are essential to maximize the strengths of different knowledge bases and skills.

Table 11.6.1 Questions guiding local-level action

<i>How do we make the case?</i>	By doing a local needs assessment, and taking into account local and national strategies
<i>What are we aiming to do?</i>	Expressed by clear aims and objectives with indicators and targets
<i>How do we involve patients and the public?</i>	Be clear about why patients and public need to be involved and how to engage them at all stages of the strategy identifying the barriers to change
<i>How do we engage/communicate with partners?</i>	Make sure all those who are affected by the strategy are involved including clinicians and partner organizations. Identifying who will support and who will oppose and how to deal with this; communicate with all involved as the work is taken forward
<i>How can we make change happen?</i>	Securing change is the core of the work and needs to be addressed in the planning stage. This stage should include a description of the actions that are required, and an assessment of the resource implications, securing adequate resources in order for implementation to be possible and appropriate
<i>How do we know we have done what we wanted to do?</i>	Evaluate the impact to demonstrate achievement against the standards and targets
<i>How can we make change stick?</i>	Change needs to be sustained to ensure that it becomes routine practice. This may require a change in work environment with a process of ongoing monitoring and audit to stop people reverting to old patterns of working

Case study: creation of Public Health England—emphasis on partnership

As part of the healthcare reform process in England, in 2013, the public health system has been restructured by the creation of Public Health England (PHE) to reflect the need for strong central and local partnerships. The main drive for this reform is the recognition that public health is not the product of health service activity, and that addressing upstream broader social and economic determinants are key to promoting better health.

At a central level, the PHE strategy directorate will be responsible for ‘a coherent, credible and internationally recognized strategy for the transformation of the public’s health’ (PHE n.d.) providing ‘the leadership for a widely-owned strategic direction for public health that is strongly supported by local authorities, the National Health Service (NHS) and other partners’. Key to its implementation is the repositioning of local Directors of Public Health from the NHS to local government authorities that will have new duties and powers for Health and Wellbeing Boards which will use processes, such as the production of Joint Strategic Needs Assessments (JSNAs) and Joint Health and Wellbeing Strategies (JHWSs), to promulgate local plans for improving health and well-being and reducing inequalities in their local communities. It is envisaged that there will be a continuous process of strategic assessment and planning involving all sectors to ‘develop local evidence-based priorities to improve the public’s health and reduce inequalities’, and helping determine what actions local authorities, the local NHS and other partners will need to take to meet health and social care needs, and to address the wider determinants that impact on health and well-being (Department of Health 2013a).

How well these structural changes work in delivering their objectives of reducing inequalities and addressing local health needs through joint strategies will need monitoring and evaluation.

2. Environment

Environmental influences play a key role in effective intervention. At a broad level, they may be economic, social, political, and physical.

Case study: healthy settings

The healthy settings approach, which considers health promotion and disease prevention in the context of broader settings, provides an example of structuring environments to be health promoting. The WHO defines a *setting for health* as the place or social context in which people engage in daily activities in which environmental, organization, and personal factors interact to affect health and well-being. Settings are characterized by physical boundaries, a range of people with defined roles, and an organizational structure (WHO n.d. f). Examples of settings are:

- ◆ Schools.
- ◆ Hospitals.
- ◆ Cities/villages.
- ◆ Workplaces.

In healthy settings, people can create and solve problems related to health, and actively use and shape the environment. Different settings provide diverse ways to implement health strategies.

Schools have an integral responsibility and role in encouraging health promotion as part of a larger social health model. The healthy schools movement, promoted by the WHO, has played a key role in developing and sharing experiences across many countries. For example, in India, the school fostering health programme has been emphasizing that a balanced diet, regular physical activity, and lifestyle management play a key role in the prevention and control of many diseases. One of its key programmes has been to work with schools to promote the ‘Mid day Meal Program’, which encourages healthy eating and hygiene (Healthy India n.d.). The School Health Foundation of India has established a scheme for ‘Healthy School’ Certification based on the achievement of ten points of criteria (School Health Foundation of India n.d.). In Mississippi, United States, the state’s Department of Education has established an Office of Healthy Schools committed to offering technical assistance and services to enable schools and communities to create programmes, based on CDC guidance, which encourage lifelong healthy behaviours (Mississippi Office of Healthy Schools n.d.).

In England, the aims of the National Healthy Schools Programme (NHSP) are to:

- ◆ Support children and young people in developing healthy behaviours.
- ◆ Help to raise pupil achievement.
- ◆ Help to reduce health inequalities.
- ◆ Help promote social inclusion.

Health promoting schools have been characterized as having six domains for action: the formal curriculum, the school ethos, school policies and practices, school health services, school–home–community interactions, and organizational structures. National Healthy Schools also provide education and support of young peoples' personal and social health (including sex and relationship education), healthy eating, physical activity, and emotional health and well-being. The evidence regarding interventions to improve children's health indicates the value of inter-sectoral, comprehensive programmes, and these can be developed and implemented through the structure of health-promoting school programmes (Department of Health n.d.).

Hospitals are another example of a setting in which to promote health, as well as provide health services. The promotion of healthy hospitals can be described from two perspectives—through the care they give and through the lens of environmental sustainability. The initial declarations on health promoting hospitals focused on the former with statements that hospitals should:

1. Promote human dignity, equity and solidarity, and professional ethics, acknowledging differences in the needs, values and cultures of different population groups.
2. Be oriented towards quality improvement, the wellbeing of patients, relatives and staff, protection of the environment and a realisation of the potential to become learning organisations.
3. Focus on health with a holistic approach and not only on curative services.
4. Be centred on people providing health services in the best way possible to patients and their relatives to facilitate the healing process and contribute to the empowerment of patients.
5. Use resources efficiently and cost-effectively, and allocate resources on the basis of contribution to health improvement, forming as close links as possible with other levels of the healthcare system and the community. (WHO Health Promoting Hospitals Network 1997)

The US CDC on Healthy Hospital Choices strategies suggests that hospitals could engage to promote better health where recommended—promoting healthy hospital food, physical activity, breastfeeding and lactation support, and tobacco-free choices (National Center for Chronic Disease Prevention and Health Promotion 2010). However, over recent years, the responsibility of hospitals to contribute to sustainability has been a growing theme.

The NGO 'Healthier Hospital Initiative' has created a network of hospitals committed to improving not only the health of patients and staff, but also to promoting the role hospitals can play in creating a sustainable environment through engaging leadership, healthier food, cleaner energy, less waste, safer chemicals, and smarter purchasing (Healthier Hospitals Initiative 2013).

In England, the NHS has created a Sustainable Development Unit which works across health, public health, and social care to help health and care organizations to fulfil their potential as

leading environmentally sustainable and low-carbon organizations (NHS n.d.).

These roles of hospitals and healthcare facilities in civil society as providers of care, as providers of employment, and as influencers of the local environment and the local community are often forgotten.

Cities/villages are also important healthy settings as they encompass the overarching areas where people live. The WHO healthy cities project (WHO n.d. g) is a global movement established to create health-supportive environments, which will enable the achievement of good quality life. They focus on ensuring basic sanitation and hygiene needs are met, as well as ensuring access to healthcare. In Europe, the primary aim is to put health high on the social, economic, and political agenda of city governments, and engage all sectors to provide policies and plans to address inequality and urban poverty, and address the needs of vulnerable groups and the social, economic, and environmental determinants of health (WHO Europe Office n.d.).

Workplaces are other important settings where health should be promoted. Just as the younger population spends most of their day at schools, adults usually spend more time at their workplaces than in any other setting. Workplaces can support programmes aimed at improving the health conditions and awareness amongst workers/employees for mental, as well as physical, well-being:

Providing a psychologically safe workplace is no longer something that is simply nice to do, it is increasingly becoming a legal imperative. (Mental Health Commission of Canada 2013)

The WHO healthy workplace model suggests a comprehensive way of thinking and acting that addresses:

- ◆ Work-related physical and psychosocial risks.
- ◆ Promotion and support of healthy behaviours.
- ◆ Broader social and environmental determinants (WHO n.d. h).

The programme for Health at Work seeks to ensure a positive approach to health and work which includes training managers to be aware and communicate about well-being and mental ill health, as well as encouraging a culture of health (mental and physical) at work. This approach highlights the mutual benefits of health and productivity, linking traditional health and safety with well-being initiatives (Healthy Workplaces 2011).

This positive approach to health is demonstrated by the replacement of sick certificates with 'fit notes' in the United Kingdom. Introduced in April 2010, fit notes are issued to individuals by doctors to provide evidence that they 'may be fit for work' or 'not fit for work' (Department for Work and Pensions n.d.).

3. Outcome-focused

A strategy that is *outcome-focused* ensures an optimal investment of available resources with the greatest health gains through the monitoring of health outcomes. Focusing on outcomes can help programmes measure the successes and failures of what has already been implemented, and allow room for evaluation, adjustment, and improvement.

Case study: public health outcomes in England

An example of outcome-focused strategies is the use of health inequality targets in England. These targets and headline indicators were initially promulgated in 2006 as part of a national strategy to promote health, and identified 14 areas for measurement

(Department of Health 2006). Two health inequalities targets on infant mortality and life expectancy in addition to 12 headline indicators for areas in which evidence suggested actions could lead to a greater emphasis on prevention were proposed. These have subsequently been refined and published as the *Public Health Outcomes Framework for England 2013 to 2016* (Department of Health 2013b), which has the outcome targets of increased healthy life expectancy and reduced differences in life expectancy and healthy life expectancy between communities, as well as indicators in four domains: improving the wider determinants of health, health improvement, health protection and healthcare public health, and preventing premature mortality (Fig. 11.6.1).

This framework will guide public health action at the local level and regular monitoring will take place, allowing progress to be

tracked and performance to be compared between different geographical areas based on local authority boundaries.

4. Population-based interventions

Preventive strategies can target individuals or target populations as a whole. Placing emphasis on the whole population produces collective health benefits and can change the patterns of behaviours and disease prevalence by having a small impact on many people.

Case study: Less Salt, More Life campaign in Argentina

In 2011, bread makers in Argentina voluntarily reduced the salt in bread by 40 per cent and restaurants in Buenos Aires removed salt from their tables as part of a campaign to reduce hypertension and reduce heart disease. Discussions also took place with the

food industry on reducing the salt content of processed food. Prior to the campaign, the daily salt consumption was estimated to be two to three times that of recommended levels. Population-level salt reduction is considered to be one of the most cost-effective strategies to reduce hypertension and its consequences (He and MacGrigor 2009). The government established a national committee with cross-government representation, working with the big food companies and unions to come to voluntary agreements. The coordinated monitoring plan will evaluate progress. It is estimated that with a 3 g salt reduction in each individual's diet, 6000 cardiovascular deaths, 13,000 myocardial infarctions, and 13,000 strokes could be avoided overall (Laspiur 2012).

5. Life course approach

A life course approach addresses cumulative adverse effects on people's lives by fostering health from gestation through to old age. The risks of developing disease and disability accumulate with age and are influenced by social and physical factors at all stages of life (Fig. 11.6.2).

There are critical periods, such as gestation and early childhood and also adolescence, when environmental exposures do more harm to health and its potential, as well as sensitive developmental stages when social and cognitive factors are more easily acquired, than at other times. Thus, social behavioural and environmental factors impact on the potential for a healthy future and continue to do so throughout the life course to old age (Kuh Ben-Shlomo 1997; WHO n.d. i).

Understanding the importance of the life course has led to different initiatives to develop strategies to promote preconception care, promote optimum care in pregnancy, efforts to ensure safe delivery, a focus on vulnerable children and adolescents, and interventions tailored to promoting and maintaining health in middle and older age.

6. Empowerment structures for local action—community based initiatives

Empowerment gives everyone in the community the opportunity to achieve their full potential by gaining control over decisions and actions that influence health. There are many levels of involvement when empowering people and their communities (Box 11.6.5).

Box 11.6.5 Principles for involving the public in public health strategy implementation

- ◆ The community must be seen as being part of the solution, not the problem.
- ◆ Community representatives need mechanisms to link to the wider community.
- ◆ Community input must be accountable to the local community. Any strategy has to take into account marginalized minority groups.
- ◆ To ensure the public can truly benefit, financial support is necessary.
- ◆ The community should raise issues that are of concern to them.
- ◆ The community needs to see concrete outcomes from their voluntary involvement, otherwise, they might lose interest.
- ◆ Meetings involving the community must avoid jargon.

Box 11.6.6 Role of Diabetes UK

Diabetes UK is the leading charity that cares for, connects with and campaigns on behalf of every person affected by or at risk of diabetes. We help people manage their diabetes effectively by providing information, advice and support.

We campaign with people with diabetes and with healthcare professionals to improve the quality of care across the United Kingdom's health services.

We fund pioneering research into care, cure and prevention for all types of diabetes.

We work to stem the rising tide of Type 2 diabetes—through risk assessment, early diagnosis, and by communicating how healthy lifestyle choices can help many people avoid or delay its onset.

Case study: Partners for Mental Health

The Canadian Mental Health strategy emphasizes the need to engage patients and their carers in determining what they want from health services:

The mobilization of the Canadian public to take action on mental health issues is essential in order to ensure that mental health remains a high priority. (Mental Health Commission of Canada n.d.)

Partners for Mental Health 'has one focused goal...to catalyze a social movement that will empower individuals and organizations to take action to improve mental health' and in particular to engage with the general public to increase engagement in and advocacy for mental health issues. (Mental Health Commission of Canada n.d.97)

Effective strategy implementation also relies on community engagement and the conciliation of top-down directives with bottom-up initiatives. As such, it is important to engage the public and patient groups in implementation as their lack of engagement will result in a failing strategy. Ways of engagement may be through minimum participation, where people are merely passive receivers of information, for example, receiving health education materials or through active partnership, in which patient groups or the public are partners, empowered to play expanded roles and to take responsibility. For example, Diabetes UK plays a pivotal role in providing advocacy and advice for diabetic patients at national and local levels (Box 11.6.6).

The PEOPLE framework provides a useful conceptual framework for strategic planners.

Delivering public health strategy**Health service contribution: the role of primary care**

How public health services are delivered is obviously key to their effectiveness not only in dealing with disease, but in promoting better public health. We have already referred to the structural changes in England which are based on enabling a greater focus on the determinants of health. At the same time, the role of health services and of public health within health services is important for delivering better health outcomes. For example, providing

antenatal care, well-baby checks, postnatal support, and immunizations are all part of a public health service delivered in different places by different systems including within a primary care setting or within a government-run maternal or child health clinic. As such, public health services need to be considered within the framework of primary care provision.

That primary care should be the foundation of health services has been recognized by many countries who strive to develop or strengthen their public health and healthcare systems. The need to enhance primary care, based on the principles of Alma Ata, has been reaffirmed in the World Health Report 2008, *Primary Health Care: Now More Than Ever* (WHO 2008) and further highlighted in the 2009 WHA's resolution on primary care policies (WHO 2009b).

In comparison with systems based on specialist care, primary care produces better population health outcomes, reduces the rate of avoidable mortality, improves continuity and access to healthcare, results in higher patient satisfaction, and reduces health-related disparities at a lower overall cost for healthcare (Starfield 1998). It contributes to the health of the population through a wide range of services, which include:

1. Health promotion and proactive management of diseases:
 - ◆ Immunization.
 - ◆ Promotion of healthy lifestyles.
 - ◆ Risk assessment and reversal.
 - ◆ Screening of health-related problems and diseases.
 - ◆ Appropriate treatment and prevention of disease complications.
 - ◆ Enabling management of illness and disability.
 - ◆ Supportive and palliative care for end-stage disease.
2. Ambulatory treatment of acute diseases.
3. Supporting health protection and promotion within the community.
4. Planning and coordinating care of individuals at all levels and across different healthcare professionals.

Primary care health services provide ongoing care at a community level and, as such, they are often closely interrelated with public health services. In many situations, primary care clinicians are indeed the main providers of public health services and increasing attention is being paid to effective and efficient models for integrating personal healthcare and public health, and organizing primary care on the principle of care for individuals in the context of an identified population over time. To quote Van Weel et al. (2008):

The future of primary care, and health care in general, will depend on how effectively primary practices achieve this community-oriented primary care approach and contribute to equity and social cohesion. Current efforts to revitalise primary health care worldwide should go hand in hand with attention to the social determinants of health. Just as the social determinants' approach to improving health equity must involve health care so must programmes to control priority public health conditions include attention to the social determinants of health.

Now More Than Ever (WHO 2008) emphasizes yet again how implementing primary care strategies needs to be context specific, in particular with reference to income and resources. For example, the Chinese healthcare system is investing significantly in community health centres and community-based systems to

provide universal access to primary care, to emphasize prevention, to enable choice between Western and traditional medicines, and to strengthen programmes within local communities.

The primary care strategy of the reforms in China aims to strengthen the establishment of the public health service system by:

- ◆ Building sound public health networks of disease prevention, health education, maternal and child healthcare, mental health, first aid, blood collection and supply, health supervision, and family planning.
- ◆ Improving the public health functions of the medical services system based on a basic medical services network.
- ◆ Setting up an information-sharing and resources-sharing public health services system.
- ◆ Enhancing the capacity of public health services.
- ◆ Enhancing the capacity to respond to public health emergencies.
- ◆ Decreasing the urban–rural inequity in utilization of public health services. (Government of China 2009)

Another example of the promotion of the strategic focus for healthcare reform through developing primary care services to deliver public health comes from Chile. In Chile, the health policy has defined a detailed benefit package, which is well publicized among the population as an enforceable right. People are being informed about the kind of services, including access to specialized care, which they can claim from their primary-care teams. In combination with sustained investment, such unambiguous entitlements create a powerful dynamic for the development of primary care (WHO 2008, chapter 6).

The public health workforce

Improving public health requires the combined efforts of people from many professions and disciplinary backgrounds (Sim et al. 2007).

For example, voluntary NGOs frequently have greater insights into the health needs of disadvantaged groups within communities than do statutory organizations. As such, it is not enough to focus on any one sector or any one activity but to recognize the interactions and different levels at which these influences are working. In the United Kingdom, public health practice is recognized as having three overlapping domains of health protection, health improvement, and health services (HM Government 2010). This structural framework recognizes the interactions between the different aspects of practice and that practice needs to be underpinned by an understanding not only of epidemiology and biostatistics, but of ethical issues within a global context.

The workforce in public health is multidisciplinary. The formal definition of a public health professional is a person educated in public health or a related discipline who is employed to *improve health* through a *population focus* (Institute of Medicine 1988). A useful way of considering the workforce, adopted in the United Kingdom, is that there are three main groupings: (1) specialists; (2) those who practise public health as part of their role, such as primary care workers; and (3) those with an interest whose work impinges on the public's health. In the United Kingdom, specialists are those who have demonstrated a high level of competence in proscribed areas and public health specialist training is defined

by competency acquisition through work-based placements. This approach is based on the historical origins of the public health specialty which derives from the role of the nineteenth-century Medical Officers of Health, instituted as key players in the sanitary reforms which accompanied the Industrial Revolution. Incorporated into the NHS in 1974 and recently again relocated in local authority government, their descendants need no longer be doctors but need to have acquired competence in nine levels of public health practice:

1. Surveillance and assessment of the population's health and well-being.
2. Assessing the evidence of effectiveness of health and healthcare interventions, programmes and services.
3. Policy and strategy development and implementation.
4. Strategic leadership and collaborative working for health.
5. Health improvement.
6. Health protection.
7. Health and social service quality.
8. Public health intelligence.
9. Academic public health.

Standards of specialist practice are maintained through a professional body, the Faculty of Public Health (n.d.), which oversees:

- ◆ The quality of specialist training.
- ◆ Professional development of public health specialists in the United Kingdom.
- ◆ Maintenance of the professional standards in the discipline.

Some overseas countries adopt a similar approach and standards including the Hong Kong College of Community Medicine (n.d.), which is part of the Hong Kong Academy of Medicine. The Academy is an overarching medical body representing the professional groups in medicine (Hong Kong Academy of Medicine n.d.). The Colleges within the Academy are professionally led and independent of government or licensing bodies. Their remit is to set professional medical standards and curricula from postgraduate to specialist levels. Licensing bodies, such as the UK General Medical Council (n.d.) or the Hong Kong Medical Council (n.d.), act as professional regulators and issue the licences to practise.

In the United Kingdom, where senior public health specialists may come from a variety of professional backgrounds, a voluntary register was created using equivalent standards of competence to medical counterparts. With the many changes in the United Kingdom, public health specialist regulation is currently under review.

Defining specialist professional training and standards is a less daunting challenge than harnessing the contribution of the wider workforce because it is enormous, diverse, diffused, and often ignorant of its own potential for improving health. An attempt was made by the English Department of Health to establish regional Teaching Public Health Networks to enhance communication and coordinate wider training. The networks were intrinsically collaborative and sought to break down historical boundaries between the further and higher education sectors, and barriers between education, health, and other sectors (Sim et al. 2007). However, the current English reorganization of public health means that the

complex future challenges will require the re-engagement of many people, from specialists and practitioners to a wider workforce, in new organizational arrangements currently being developed by PHE.

In the United Kingdom, further education has traditionally focused on acquisition of practical job skills and this has been the basis of public health training. In other countries, greater emphasis has been placed on academic training and qualifications, particularly acquisition of Master degrees in Public Health, often provided by academics working in Schools of Public Health. In the United States, there is an active system of accreditation of Schools of Public Health through the Council on Education for Public Health (CEPH) (n.d.) and a set of agreed competencies for MPH programmes (Association of Schools & Programs of Public Health (ASPPH) n.d.). However, since public health is a dynamic and constantly developing field, it is always under review and the ASPPH's 'Framing the Future' Task Force has launched a Master of Public Health (MPH) Expert Panel to update the MPH for the twenty-first century (ASPPH 2012). In addition, greater focus has been placed on defining learning objectives for the growing field of undergraduate education, often to be found in Liberal Arts Colleges thus underlining the multidisciplinary approach to public health practice.

Public health education in China

In contrast to the humanities-based courses of the United States, public health education in China remains embedded in medical education and the initiation of MPH degrees is a recent and rapidly developing movement. The origins of public health practice lie in the Sanitary Departments established in 1905, but many public health functions were implemented by police and other interdisciplinary groups. Municipality public health administrations followed German models and early public health campaigns were organized by interdisciplinary working groups rather than individuals with specialized public health education. In 1928, the National Ministry of Health had four foci, which included training health personnel including a focus on public health skills.

A blueprint for establishing provincial health bureaus that included an education and propaganda department was established and Ministry field stations started postgraduate training programmes for public health-oriented jobs, such as public health officers, sanitary inspectors, and public health teachers for schools.

After 1949, the public health education system, like all the educational structures, was substantially transformed. Patriotic health campaigns focused on mass mobilization, balanced preventive and curative strategies, and incorporated elements of traditional Chinese and Western medicine. A mainly biomedical model of public health emerged in line with the Soviet model with five major disciplines, namely, school hygiene, occupational hygiene, food hygiene, environmental hygiene, and radiation hygiene.

China's 'barefoot doctor system' was instituted in the late 1960s, producing a cadre which was a hybrid between clinical physician and public health practitioner who provided vaccines, created water and sanitation systems, improved stoves and toilets, provided basic medical care, assisted in family planning policies, and collected information about epidemics. Structures of undergraduate- and graduate-level public health training re-emerged in 1978 in China, with much of the curricula and format deriving from international models.

Public health and pre-clinical medical students now take a common-stem curriculum during the first several years of training. Four years of basic science and clinical requirements are generally followed by 1 year focused on various aspects of public health. Chinese CDCs are the major employer of graduates but increasingly strong links are being forged with local academic departments.

Traditional Chinese medical school curricula are being restructured at many institutions, providing an important opportunity to expand the role of public health education. Within China, there are regular meetings among School of Public Health deans to share ideas and experiences for improving public health education as well as international meetings with counterparts from the United States (Bangdiwala et al. 2011).

Research

As discussed in earlier chapters, public health research remains underfunded in most jurisdictions despite the importance of the evidence base to guide effective policies and professional practices. High-tech medical proposals with quick returns are often more attractive to funders.

Earlier in the chapter we have stressed the importance of evaluation and monitoring health interventions as key components of the strategic approach. Increasingly, strategies are developed which recognize the inter-relationship between health and health services. For example, in the United Kingdom when launching *Investing in Research, Improving Health*, the responsible Minister wrote:

We are committed to tackling disease prevention wherever possible and are excited by the emerging understanding of the biological links between inequalities and health. The benefits to health and healthcare are explicit but we are also alert to the potential for economic benefits. The life sciences have a key part to play and a tradition of excellence on which to build. (Chief Scientist Office, NHS Scotland 2009)

In England, the National Institute for Health Research has an arm which focuses on public health. The Public Health Research (PHR) programme commissions research to provide new knowledge on the benefits, costs, acceptability, and wider impact of non-NHS interventions (NHS 2013) (Fig. 11.6.3).

However, as in other countries such as Australia, the lion's share of available funding goes to basic sciences and clinical research, with allocations to public health and health services research in single-digit figures (Australian Government National Health and Medical Research Council 2008).

Barriers to implementing strategy

Whilst many organizations produce strategies, many do not achieve their goals. To some extent this is because they are aspirational and at times unrealistic. Management literature suggests that there are four main barriers to effective strategy implementation. These are:

1. *The vision barrier*: in the age of the knowledge-based economy, the workforce needs to understand the strategy.
2. *The people barrier*: personal incentives need to be tied to the long-term initiatives supporting the strategy, not to short-term (financial) results.

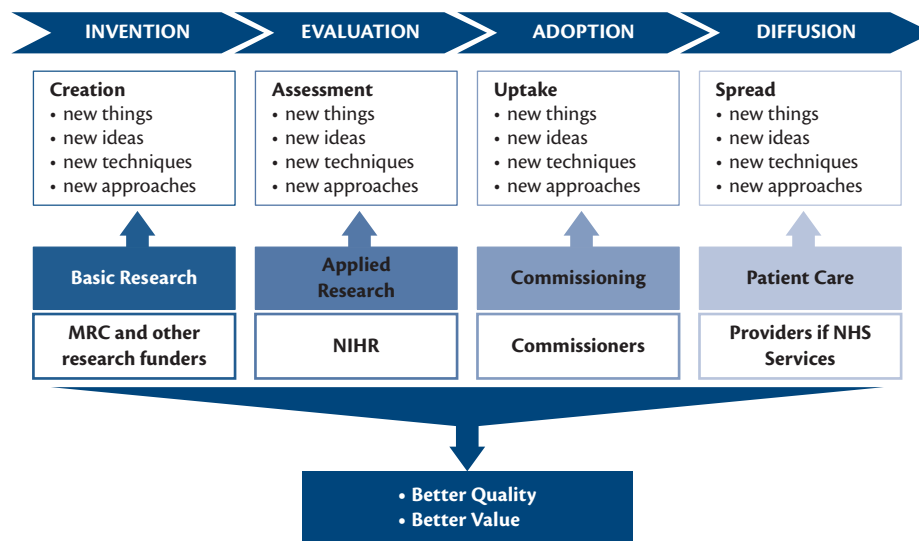

Fig. 11.6.3 The research pathway.

Reproduced with permission from The National Institute for Health Research (NIHR), *NIHR Briefing Note 1.1*, Version 9, Copyright © 2014, available from <http://www.nihr.ac.uk/files/pdfs/Briefing%20documents/1.1%20The%20National%20Institute%20for%20Health%20Research.pdf>.

3. *The resource barrier*: strategies need to be linked to budgets.

4. *The management barrier*: managers need to discuss strategies but often focus on budgets (Kaplan and Norton 2001).

Thus, there may be over-attention being paid to the day-to-day duties rather than tackling the projects that have been identified as key to organizational sustainability and success. Important strategies may be perceived as overwhelming and too difficult to tackle. Lack of teamwork can inhibit cooperation across organizational divisions and different players have different priorities. Recommendations for successful implementation of strategic plans include:

- ◆ *Focus*: having too many priorities means no action and not everything can be or is a priority, so agree on what the top two to three goals are.
- ◆ *Communicate clearly and often*, and understand each other's language and contextual background.
- ◆ *Emphasize and reward teamwork* which may involve trade-offs, negotiation, and difficult conversations about resource allocation and expectations.
- ◆ *Regular review of progress*: provide a framework for ensuring that all stakeholders reach their objectives.
- ◆ *Accountability needs to be clearly defined*.
- ◆ *Emphasize implementation* of the strategic plan is the most important aspect of planning.

Identifying the barriers to implementation and overcoming them is a key success factor for any organization. Teamwork, accountability, and resolution of conflicting priorities, or hidden agendas, will help ensure the implementation of the top two to three goals (Dane 2010).

Conclusion

This chapter has focused on strategies for promoting public health and structures for their implementation. As the scope

of public health broadens and more consideration is given to the wider determinants of health and to the challenges of the future—the NCD epidemic, changing patterns of demography and disease, and climate change and its impact on health—more partners will need to be involved in signing up to strategies to tackle the threats they pose to public health. The example of SARS in 2003 demonstrated the problems that can occur when a strategy is missing. The experiences of China during its economic opening up demonstrate the need to constantly review the impact of broader determinants on equity in health and health services. Different examples of evidence-based and value strategies have been discussed with reference to examples and experiences in different countries and settings. The need for fit-for-purpose structures in the health systems, public health workforce, and research community has been highlighted and barriers to achieving the strategic goals described. All too often strategies remain merely fine words. The fundamental challenge is their implementation and continuous refinement in the light of delivery.

Strategies for health services

Chien Earn Lee

Introduction to strategies for health services

The previous edition of this chapter started with two questions. Firstly, why public health professionals should be interested in health services, which led to the second question: do health services actually make a meaningful contribution to population health?

Writers such as McKeown (1979) contended that the main drivers of improvements in health had been nutrition, environment, and behaviour rather than healthcare. He showed that three-quarters of the decline in mortality in England and Wales between 1841 and 1971 had been due to a reduction in deaths from infectious disease and that three-quarters of this reduction had preceded the widespread introduction of immunization or antibiotics.

Others such as Illich (1976) argued that instead of improving health, healthcare has a direct and adverse effect on health, for example, side effects of prescribed drugs, hospital-acquired infections, poorly performed surgery, and the consequences of following up spurious abnormalities from the increasing numbers of laboratory investigations.

However, as several commentators have noted, McKeown was describing a period in which healthcare still had relatively little to offer. It was only in the 1960s and 1970s that safe and effective drugs for many chronic diseases became widely available (Nolte and McKee 2004). Contrary to the situation before the 1960s, health services are now making an important contribution to overall improvements in life expectancies in industrialized countries. Many new treatments have been introduced that have been shown, in high-quality evaluative research, to prolong life. Examples include effective treatment for hypertension and heart failure, secondary prevention following myocardial infarction, and chemotherapy for many childhood cancers.

International differences provide many natural experiments to examine this issue further (McKee and Bojan 1998). For example, prior to 1990 the death rates from causes amenable to medical care (i.e. deaths from causes that are potentially preventable with timely and effective healthcare) were higher in former communist countries of Central and Eastern Europe than in the West (Bojan et al. 1991; Boys et al. 1991). Excluding early neonatal deaths, for which only incomplete data are available, Velkova et al. (1997) estimated that amenable causes accounted for 24 per cent of the East–West gap in male life expectancy between birth and the age of 75 years in 1988. The corresponding figure for females was 39 per cent.

There is now considerable evidence that, unlike the situation prior to the 1970s, health services, although only one of the determinants of health, others being genetic predisposition, individual behaviour and lifestyle, and environmental circumstances, can make a substantial difference to population health (McKee and Figueras 2009).

The Ottawa Charter for Health Promotion (World Health Organization 1986) recommended the reorientation of health services and their resources, beyond its responsibility for providing clinical and curative services, towards the promotion of health. The Charter also emphasized the need to work towards enhancing life skills to increase the options available for people to exercise more control over their own health and over their environments and to make choices conducive to health.

Public health professionals have a key advocacy role to ensure that resources in hospitals (which invariably receive the lion's share of the healthcare budget) are used effectively, efficiently, and equitably to optimize outcomes, and that community-based services which are less urgent but no less important than acute services are not neglected. The capabilities of public health professionals in developing systems-based solutions and mobilizing intersectoral action will need to grow to improve population health.

The remainder of this chapter explores the changing context of healthcare services, the emerging themes in healthcare services, and strategies for delivering and improving healthcare services.

The context for healthcare services

Healthcare services do not exist in a vacuum. While this statement seems self-evident, it has often not been adequately taken into account in developing and evolving healthcare strategies. As a result, strategies have either not taken root (especially those related to 'transplanted' best practices from other systems) or like the proverbial frog being slowly boiled alive, failed to respond in a timely manner to meet new challenges. Contextual factors that need to be considered include societal and professional norms and values as they influence the central principles of the system as well as the desire for reform. Economic factors such as the level of economic development would affect the level of disposable resources available for health services (Maxwell 1981), while the upward pressure on healthcare expenditures has been the key driver for healthcare reforms around the world. Healthcare systems must also be able to respond proactively to factors affecting population health needs such as the changing demographics and patterns of disease as well as the impact of technological change. The role of education in producing sufficient professional and managerial

capability will also influence the health system's capacity for serious and sustainable action. These contextual factors are discussed here under the headings of defining norms and values, the reality of macroeconomics, demographic pressures, changing disease patterns, technological changes, the quest for quality and reducing waste, and rising patient expectations.

Norms and beliefs

Healthcare systems act as mirrors that reflect deeply rooted social and cultural expectations of the population that they serve (Contandriopoulos et al. 1998). Although these norms and beliefs are generated outside the formal structure of the healthcare system, they play a major role in defining the system's overall characteristics.

Societies have dominant belief systems where the daily tensions between differing values and beliefs in a society are held in relative stability (Benson 1975). A useful approach to understanding belief systems sees these tensions as grouped around four poles (Habermas 1987): values, understanding of phenomena, definition of jurisdictions and allocation of resources, and logic of regulation.

In this framework, values include the tensions and trade-offs between equity, individual autonomy, and efficiency (Clark 1988). Understanding of phenomena relates to how concepts such as life, death, sickness, health, and pain are interpreted and thus viewed as relating to the objectives of a healthcare system (Gillett 1995). Definition of jurisdictions and allocation of resources comprise the perceptions of the role and functions of those working in the healthcare sector, as well as the allocation of resources between prevention and cure and between healthcare and broader determinants of health. The logic of regulation relates to how society chooses to regulate the delivery of healthcare. This may be technocratic with trained experts guiding the system on the basis of their knowledge and position within the hierarchy; professional self-regulation which has the physician (as the best agent of the patient) at the centre of the system; the market-based model in which regulations reflect supply and demand in a competitive market; or the democratic model, in which the population, either directly or, more often, through elected or appointed representatives, is responsible for setting out the framework for delivery of healthcare.

An understanding of the dominant belief system in a society is important for public health professionals as it contributes to knowledge of why systems are as they are, how they have changed, and the objectives that individuals within the healthcare system are pursuing. It will also influence the choice of strategies that should be adopted to bring about meaningful and sustained change (McKee and Figueras 2009). For example, some societies view healthcare as predominantly a social and collective good. Such societies would more readily accept policies designed to create intentional cross subsidies, from young to old, rich to poor, and from healthy to sick, than societies that view healthcare as a commodity that can be bought and sold in the market.

Norms and beliefs can and do evolve over time. For example, years of spectacular growth have seen more people pulled from abject poverty in modern Asia than at any other time in history. But as they become more affluent, the region's citizens want more from their governments. Across the continent, pressure is growing for public pensions, national health insurance, unemployment

benefits, and other hallmarks of social protection. As a result, the world's most vibrant economies are shifting gear, away from simply building wealth towards building states with better and more comprehensive welfare provisions (*The Economist* 2012). While such changes increase the demands on healthcare systems, they also provide opportunities to introduce changes and strategies that may not have been acceptable based on previous norms and beliefs.

Macroeconomic factors

The historically high rates of economic growth seen during the 1960s and 1970s have not been sustained in the 1990s. This has been compounded by economic volatility with shorter boom and bust cycles with globalization. With economies across the world becoming more and more connected to one another, adverse economic conditions in one country can rapidly spread to other countries and escalate to global proportions, as was seen in the global financial crisis in the late 2000s.

At the same time, the expansion of healthcare coverage both in terms of scope of services and population covered is adding significantly to the upward pressures on healthcare expenditure. There are already concerns that the current level of expenditure on healthcare is not sustainable and is adversely affecting other sectors of the economy. For example, the United States spent more than 17 per cent of its gross domestic product on health, raising concerns about the heavy burden placed on companies doing business in the United States which can put them at a substantial competitive disadvantage in the international marketplace.

The macroeconomic environment influences the political decision-making process, in particular, the allocation of resources to competing sectors. The growth in health spending slowed or fell in real terms in 2010 in almost all Organisation for Economic Cooperation and Development (OECD) countries, reversing a long-term trend of rapid increases. Overall, health spending grew by nearly 5 per cent per year in real terms in OECD countries over the period 2000–2009, but this was followed by zero growth in 2010. Preliminary figures for a limited number of countries suggest little or no growth in 2011. Countries like the United Kingdom that invested heavily in healthcare in 1990s are having to scale back in the face of the tightening economic situation. The UK government aims to deliver £20 billion (4 per cent) efficiency savings in the National Health Service (NHS) by the end of 2014–2015. The challenge at present is how to balance increased demand from patients with the requirement for productivity and efficiency, whilst maintaining excellent, quality care.

Demographic pressures

Dr Gro Harlem Brundtland, former Director-General of the World Health Organization, called ageing one of humanity's great achievements and also one of its greatest challenges. In rich countries, the number of people over 65 who will require medical care, is expected to increase by between 50 per cent and 120 per cent from 1995 to 2025 and the elderly incur disproportionately more healthcare cost than the young. For example, in the United States, the elderly account for less than 15 per cent of the total population but incur more than one-third of healthcare spending (and this is before taking into account social or long-term care costs).

The greatest challenge lies in the developing countries. While developed countries grew affluent before they became old,

developing countries are growing old before they get affluent. The demographic shift towards an older population that took place gradually in Europe over a century, is taking place in the developing countries at a pace which far outstrips these countries' socioeconomic development. The impact of ageing on demand for healthcare is often compounded by falling birth rates, leading to an increasing dependency ratio.

It is, however, necessary to enter three caveats. Firstly a study of American Medicare data showed that while estimated lifetime cost increases with age, the cost associated with an additional year of life and the average annual cost over a person's lifetime both decreased as the age at death increased (Lubitz et al. 1995). This could be due to less intensive treatment the older the patients are in their respective last year of life (Scitovsky 1988). This suggests that healthcare cost will be more substantially affected by the expected increase in the absolute number of elderly people than increased longevity beyond the age of 65.

Secondly, the health and social profile of the elderly of the future may be different from current elderly. They are likely to be better educated and would have benefited from a lifetime of better nutrition. On the other hand, they are also likely to have adopted a more sedentary lifestyle and have higher expectations of healthcare. For these reasons, we should not make simplistic extrapolations of demand based on current data of the elderly to a future population.

The final caveat is that pessimistic predictions of the costs of ageing are based on the assumption that health services will continue to expand in their current form which is highly hospital centric. The impact of ageing on disease burden and costs can be moderated by greater emphasis on prevention of disease and disability and transforming models of care for the elderly.

Changing healthcare workforce

Specialization in the pursuit of greater knowledge and expertise has characterized scientific progress in medicine for nearly two centuries (Cassel and Reuben 2011). A more recent development is the creation of subspecialties, recognizing that there are some specific populations of patients who would benefit from the highly focused knowledge and skills obtained by additional training and certification beyond that of a 'general' specialist. As these tertiary subspecialists require high patient volume to maintain proficiency in their skills, they are usually based at referral centres.

Many new and emerging subspecialties are cross-disciplinary. In the United States, sleep medicine crosses six different specialties, and palliative medicine is a subspecialty option for ten different primary specialties. The proliferation of specialties has led to concerns that medical care would become increasingly fragmented with the concomitant loss or undervaluing of the generalist physician with decreased attractiveness as a career choice for young doctors.

As trade barriers come down, the forces of globalization have increased the movement of all types of professionals throughout the world, and healthcare is no exception. Richer countries are increasingly relying on immigration as a means of coping with domestic shortages of healthcare professionals. This trend has led to concerns that the outflow of healthcare professionals is adversely affecting the healthcare system in many of these source countries. Insufficient human resources for health in developing countries have been identified as one of the main constraints

limiting progress on such initiatives as 3by51 and the Millennium Development Goals (MDGs) (Institute of Medicine (IOM) 2004). Recipient countries on the other hand need to develop the means to effectively assimilate the influx of healthcare professionals from diverse backgrounds and cultures.

Countries are also exploring expanded scope of practice for healthcare professionals as a means of addressing access-to-care problems. Nurse practitioners, physical and occupational therapists, and other allied healthcare professionals are growing in independence from physicians' oversight. For example, several states in the United States have passed legislation allowing pharmacists limited ability to evaluate and manage drug regimens as well as dispense drugs.

Changing burden of disease

The term 'epidemiological transition' refers to the complex changes in patterns of health and disease as societies develop. It describes the interactions between these patterns and their demographic, economic, and sociological determinants and consequences.

In the classical (Western) model, Omran (1971) described the transition from the Age of Pestilence and Famine with its high mortality and low average life expectancy (20–40 years), through the Age of Receding Pandemics, to the Age of Degenerative and Man-Made Diseases with its relatively low levels of mortality (average life expectancy of more than 50 years) and morbidity overshadowing mortality as an index of health.

Although the classical model assumes linear unidirectional change, counter transitions have also been observed where age-specific mortality rates rise rather than fall over time due to causes such as the HIV/AIDS pandemic in sub-Saharan Africa (Gaylin and Kates 1997). There is also an emerging awareness of old problems that never went away resulting in an overlap of eras, often with large disparities emerging between and within countries. On the other hand, although chronic diseases such as diabetes have usually been considered as diseases of affluence, four out of five people with diabetes now live in low- and middle-income countries (International Diabetes Federation 2012). In short, health systems in these countries must continue to grapple with the unfinished agenda of communicable diseases while addressing the new agenda of non-communicable ones in an ageing population.

As the burden of disease is dynamic (Murray and Lopez 1996), the configuration of health services must evolve accordingly to meet the changing health needs of the population. Health services cannot remain trapped in structures designed for a time when disease patterns were different. For example, the increasing incidence and prevalence of chronic diseases requires health systems to organize health services with greater emphasis on prevention and community-based services instead of the current hospital-centric model which is more suited for acute episodic care.

Current care delivery models are, however, often overly complex and uncoordinated, requiring many steps and patient 'hand-offs' that slow down care delivery and decrease safety. Healthcare organizations, hospitals, and physician groups also typically operate as separate 'silos', acting without the benefit of complete information about the patient's condition, medical history, services provided in other settings, or medications provided by other clinicians (IOM 2001).

Public health professionals have a central role in tracking and explaining trends in diseases (including predicting emerging

trends), designing mechanisms to address them, supporting the changes in service delivery that are required, and monitoring responses to these changes. With appropriate interventions, Olshansky (1986) has postulated the 'Age of Delayed Degenerative Diseases' as the fourth stage of the epidemiological transition.

Technological changes

The pace of change in healthcare is steadily accelerating. Hip replacements have been joined by knees, shoulders, and finger joint replacements. Transplant surgeons have added heart, liver, and pancreas transplants to their initial successes with kidneys. AIDS has been transformed from a rapidly progressive fatal disease to one in which increasing numbers of patients are keeping the disease under control with complex cocktails of antiviral therapy. The list is almost endless.

The growth of healthcare technology is widely held to have contributed substantially to the upward pressure on healthcare expenditure. For example, the rapid growth in cardiology services throughout the developed world is driven more by angioplasty and other technological advances in care than by changes in the prevalence of heart disease (Dash et al. 2009). Although its precise contribution is controversial (Mossialos and Le Grand 1999), a study by the Health Care Financing Administration estimated that approximately half of the growth in real per capita healthcare costs in the United States is attributable to the introduction and diffusion of new medical technology for the 1940–1990 period, within an estimated probable range of 38–62 per cent of growth (Smith et al. 2000).

There are various reasons for this increase. New technologies are often more expensive than the ones they replaced. Even where the actual technology is less expensive, it may lead to increased costs as other aspects of the service are reorganized to reflect changing patterns of treatment. For example, the introduction of new treatments may lead to an expansion in the number of individuals with indications for treatment, either because a previously untreatable condition becomes treatable or, as side effects or contraindications are reduced, the threshold for treatment falls. Finally, the diffusion of technology from tertiary centres, in some cases into primary care, can markedly reduce barriers to access and thus increase uptake.

Since the 1980s, there has also been an unparalleled revolution in the pace and volume of communication. The development of new ways of storing and delivering knowledge has transformed the way healthcare services are delivered and used, bringing benefits but also risks. It enables the separation of assessment from service provision allowing healthcare professionals to seek and provide advice without the need for face-to-face consultation. Telemedicine has led to the expansion of roles and the need for new competencies in healthcare workers. It also provides opportunities to optimize the value of highly trained subspecialists by making their expertise accessible to a wider patient population through physician-to-physician telemedicine approaches.

Quest for quality and reduction of waste

In tandem with the rapid growth in medical science and technology, healthcare is becoming more complex with more to know, more to do, more to manage, more to watch, and more people involved than ever before (IOM 2001). Healthcare systems have, however, struggled to translate knowledge into practice. For

example, it takes an average of 17 years for research evidence to reach clinical practice (Green et al. 2009). Small-area variation studies by Wennberg (1984) showed that decisions by clinicians in different areas regarding patients presenting with identical complaints could vary by as much as 40 per cent.

Geographical variation of expenditure has also been identified. For example, in 2004, per capita spending on health ranged from roughly \$4000 in Utah to \$6700 in Massachusetts in the United States (Congressional Budget Office 2008). Higher spending does not necessarily mean better outcomes. The primary reason for such variations has been previously cited as clinical uncertainty about the most appropriate treatment in any given circumstance (Anderson and Mooney 1990). This position is, however, becoming increasingly untenable as medical knowledge advances and evidence-based practice guidelines are developed for many conditions.

Healthcare systems are also grappling with the consequences of unsafe care. A study in *The New England Journal of Medicine* (Landrigan et al. 2010) reported that 25 per cent of hospitalized patients are harmed by medical errors. IOM's landmark study 'To Err is Human' (1989) estimated that there were 98,000 annual deaths from medical errors in the United States. The IOM's follow-up publication 'Crossing the Quality Chasm' has identified six dimensions where healthcare needs to improve:

- ♦ Safe—reducing harm to patients.
- ♦ Effective—providing appropriate care based on scientific knowledge to avoid underuse or overuse of services.
- ♦ Patient-centred—providing care that is based on what matters to patients taking into account their preferences, needs, and values.
- ♦ Timely—reducing unnecessary delays that may compromise care outcomes.
- ♦ Efficient—avoiding waste not just of material resources but also ideas and energy.
- ♦ Equitable—providing consistent quality of care regardless of personal characteristics such as gender, ethnicity, geographic location, and socioeconomic status.

Inappropriate care and errors waste precious resources. Waste occurs not just at the individual clinician–patient interface but as a result of poor coordination between providers and across sub-sectors, inadequate management of capital resources, and operational budgets. The IOM committee that produced the report 'Best Care at Lower Cost: The Path to Continuously Learning Health Care in America' estimated that there was \$750 billion in unnecessary health spending in 2009 in the United States alone. The IOM Committee recommended a more nimble healthcare system that is consistently reliable and that constantly, systematically, and seamlessly improves. Healthcare systems must learn by avoiding past mistakes and adopt newfound successes.

The International Cochrane Collaboration has played a major role in providing evidence of what healthcare interventions can (and cannot) achieve by undertaking systematic reviews of available evidence in the literature using standardized methods, and disseminating the information (Chalmers and Altman 1995). Unfortunately such information is not always translated into daily practice as it challenges traditional models based on clinical autonomy.

Increasing patient expectations

The development of new and more expensive technologies coupled with the ready access to information, particularly with the growth of the Internet, has led to higher and growing public expectations which may be difficult to meet.

Increasingly people are also taking over responsibility for their own care aided by online advice and other sources of information. The public increasingly expects healthcare systems to be responsive at all times (24 hours a day, every day) and that access to care should be provided over multiple channels such as the Internet, by telephone, and by other means in addition to face-to-face visits. Patients expect healthcare services to make information available to patients and their families that allow them to make informed decisions when selecting a health plan, hospital, or clinical practice, or choosing among alternative treatments.

Through the Internet, patients draw on the perspectives not only of physicians but also other sufferers from their condition. However, it comes with risks too. Those searching the web must be aware of its unregulated nature, with posts of views ranging from Nobel laureates to quacks (Eysenbach et al. 1998; Sandvik 1999). Internet prescribing may offer price savings for some, but it may also circumvent regulatory safeguards designed to reduce risks to patients.

Emerging themes in health services

This section explores some of the themes that are emerging in response to the changing context of health services. The evolving macroeconomic environment coupled with the demand for health services brought about by changing demographics, epidemiology, and patient expectations have led to a reassessment of the relationship between the state and the market as well as the way health services are organized and financed. Developments in technology underpinned by changes in norms and beliefs are challenging traditional hierarchies and stimulating new ways of delivering health services with greater involvement of patients in their own care. These themes will be considered in turn.

State and market

During the 1980s and 1990s, many countries began to re-examine the role of the state in the regulation, funding, and delivery of health services. Countries where the state has played a central role are exploring new pluralistic solutions with involvement of a range of actors at varying distances from the state. Some functions are being devolved to local government or to statutory agencies at arm's length from government or transferred altogether to private ownership. Conversely, countries in which the state has traditionally played a less central role, acting only as a source of regulation between competing private interests, are now reassessing the need to expand their role and intervene more actively (Saltman and Figueras 1997).

It would be quite wrong, however, to see these developments as a process of convergence to some ideal model of a health system. Instead, the situation in each country represents the complex interplay of the economic, social, demographic, epidemiological, managerial, and technological forces described earlier and deep-seated cultural beliefs. The debate is often characterized as a dichotomy between the state and the market but this is a gross oversimplification (Saltman and von Otter 1995). In some

instances elements of both have been combined albeit in differing proportions to allow an increased use of market-style incentives with continued ownership and operation of facilities by the public sector in quasi- or internal markets.

The introduction of market mechanisms into the health sector creates a series of conceptual and practical challenges. Conceptually, healthcare is considered in many societies as a social good, in which the provision of services to each individual is also valuable to the community as a whole, whether because of ideas of self-interest, as in the treatment of dangerous mental illness or contagious disease, or altruism. Such principles have led to the creation of systems to ensure universal coverage and solidarity. In contrast, market incentives are intrinsically based on the assumption that services provided are a commodity, with demand driven by individual preference (McKee and Figueras 2009).

Another difficulty is that the neoclassical concept of a market is based on the relationship between a buyer and a seller. However, healthcare systems typically comprise a more complex set of relationships involving the patient, various health professionals, a provider institution, and a payer, with health professionals acting as both suppliers of services and agents for the patient (Young and Saltman 1985). Finally, the assumption in neoclassical economic theory that cross-subsidies between different patients are inefficient is incompatible with the social function of the healthcare system where there are substantial cross-subsidies between young and old, rich and poor, and healthy and sick.

The key practical challenge in introducing market mechanisms into healthcare is the development of real prices. This is a tedious and expensive process which requires a robust costing system to compute the real cost (including overheads) at the service as well as patient level. Some attempts to implement market mechanisms have floundered as the transaction costs and the costly duplication of facilities to secure a competitive advantage (Saltman and von Otter 1995) outweighed the improvements in operational efficiency. Another reason for the failure of market mechanisms in healthcare is that competition operates at the wrong level. Porter and Teisberg (2006) argue that currently competition is both too broad and too narrow. Competition is too broad because much of the competition now takes place at the level of health plans, networks, hospital groups, physician groups, and clinics. Instead, it should occur in addressing particular medical conditions. Competition is too narrow because it now takes place at the level of discrete interventions or services. Instead it should take place at the patient level, addressing medical conditions over the full cycle of care, including monitoring and prevention, diagnosis, treatment, and the ongoing management of the condition.

Some other attempts have, however, been more successful. In these systems, the introduction of market principles does not mean that the government intervenes less but it intervenes differently. Even as we are familiar with market failures in healthcare, there can be government failure too—which can occur in a state- or market-based system. The manner of government intervention matters more than the fact of intervention. The purported failure of market mechanisms may at times be due more to poor implementation than the mechanism itself. Oftentimes markets fail in healthcare, because they are allowed to fail. For markets to work, government intervention such as setting the ground rules for competition and providing clear standards for market

participants with tight monitoring and evaluation as well as making prices transparent is needed.

A related issue is the changing approach to regulation. Governments need to find the appropriate balance between regulatory and competitive measures—which will change with time—depending on the context in which they are implemented. Regulation is becoming more sophisticated with greater recognition that traditional ‘command and control’ measures need to be complemented by a more extensive regulatory toolkit (which includes ‘softer’ tools such as education and community engagement). Governments also need to be cognizant of the risk of perverse incentives with poorly drafted regulations.

Many countries are beginning to question whether self-regulation of healthcare professionals can retain credibility as a system that serves the best interests of the public. Self-interest of the profession plays out in various ways, at times negatively. For example, one professional group may use the regulatory structure to exercise control and influence over another group, or to keep hold of their monopoly on very profitable services. The key question for policymakers, then, is one of governance: to what extent are healthcare professional regulators sufficiently independent of the groups they regulate—and to what extent do they act in the best interests of patients and the public? Several countries have moved to ‘shared regulation’ whereby the government and other credible experts from outside the regulated profession sit with members of the profession around the table. The proportion of places around the table is a matter for each country to determine, based on local context (Dzau et al. 2012).

Governments that have successfully incorporated market principles rely on competition and market forces to improve service delivery and efficiency, while retaining the prerogative of the state to intervene directly when the market failed to keep healthcare costs down (Atwal 2010). Markets are necessary to help government work better, and good government is necessary to help markets work better (Menon 2010). In fact some researchers have concluded that governments have to be more competent to supervise contracting and other market-style arrangements than to run services directly (Kettl 1993).

Reorganizing the system: decentralization, recentralization, and privatization

Decentralization has been defined as the transfer of authority from a high, or national, level to a lower, or subnational, level (Rondinelli 1981). Decentralization has multiple meanings, interpretations, and implementation in different countries and different contexts. The common essence of decentralization lies in strengthening local authorities through transfer of power and resources from the central government.

Decentralization has become attractive because of disillusionment with the perceived failings of large centralized, bureaucratic institutions. These include inefficiency, lack of responsiveness, and failure to innovate. Decentralized institutions are seen to have several advantages. Those working in them are better equipped to identify changing circumstances and needs, and thus can respond more flexibly. They can be more innovative than centralized institutions and they can generate higher morale, more commitment, and greater productivity. Decentralization can also facilitate enhanced partnerships with the local population, thus increasing the democratic input into policymaking.

The experience of many countries in recent years demonstrates that there are certain areas where decision-making power should not be decentralized. Four such areas include:

- ◆ Basic framework for health policy, strategic decisions on the development of health resources such as capital, personnel, expensive equipment.
- ◆ Research and development as they shape the future of the entire system.
- ◆ Regulations concerning public safety.
- ◆ Monitoring, assessment, and analysis of the health of the population and healthcare provision (as these are tools for influencing the behaviour of decentralized units).

Borgenhammer (1993) has also identified certain social and cultural conditions that are necessary for successful decentralization. These include adequate local administrative and managerial capacity, ideological certainty in the implementation of tasks, and readiness to accept several interpretations of a particular problem. Organizations undertaking decentralization must engage in a process of articulation of their mission, create internal cultures around core values, and establish mechanisms to monitor results (Osborne and Gaebler 1993).

With respect to health services, decentralization enables better access with people benefiting from the convenience of having core health services close to where they live. However, decentralization can have negative effects (Collins and Green 1994). These include fragmentation of services, loss of critical mass in services, and unacceptable variations in practice (Borgenhammer 1993). For health services there is substantial clinical evidence that centralizing certain complex conditions and procedures, specialization with co-location of specialist staff and services in facilities to generate a critical volume of cases has led to better clinical outcomes and higher productivity. The aim then is to ‘decentralize where possible, centralize where necessary’ (NHS 2007). This entails the creation of a primary and community care infrastructure that is able to deliver integrated services close to patients’ homes with consolidation of centres that perform only a small number of procedures (Dash et al. 2009).

Privatization requires separate consideration as it is fundamentally different, in several important aspects, from other types of decentralization. Its advocates argue that it brings benefits from the introduction of economic incentives for greater efficiency and higher quality in the management of healthcare (Cabinet Office 1999). It is also attractive to some governments as a means of attracting private capital into the health sector, thus reducing demands on scarce public funds.

These benefits, however, come with considerable risks. Private management and capital investment require financial returns that are consistent with those obtainable in other private markets. The pressures involved in achieving these returns can result in adverse selection (e.g. practices that intentionally discriminate against the poor and other vulnerable groups). Activities that do not generate immediate returns such as primary and secondary prevention activities are likely to be relegated to lower priority (Himmelstein et al. 1999). If privatization is not to undermine wider health policies, privatization must be accompanied by strengthened central regulatory controls. This increases administrative cost for both regulators and providers.

Two broad findings emerge from the debate on decentralization. The first is whether the advantages of decentralization outweigh the disadvantages, such as fragmented and duplicated services and high transaction costs, an issue that must be resolved on a case-by-case basis (Saltman and Figueras 1997). Secondly, a policy of decentralization requires a series of measures to create an appropriate framework, including development of a shared vision and a means of monitoring outcomes.

Ecosystem approach to healthcare

Health status is largely determined by the interaction of four linked factors: genetic susceptibility, behaviour and lifestyle, socioeconomic status, and environmental conditions (Lalonde 1974). Addressing these factors requires the concerted effort of partners outside of the traditional health sector such as in housing, agriculture and education, as well as improved coordination and continuity of care between hospital and community based services (including primary healthcare).

Healthcare systems are moving, albeit at different speeds, from an illness to a wellness/health model, shifting the allocation of funds from curative to preventive care. This is, however, a delicate balancing exercise due to the need to maintain current services while preparing for the future. The Institute for Healthcare Improvement in America has developed a framework that seeks to optimize health system performance by simultaneously pursuing three dimensions, the 'Triple Aim' of improving the patient experience of care (including quality and satisfaction), improving the health of populations, and reducing the per capita cost of healthcare (Berwick et al. 2008).

The components of the Triple Aim are not independent of each other. The pursuit of any one goal can result in changes that affect the other two, sometimes negatively and sometimes positively. For example, improving care for individuals can raise costs if the improvements are associated with new, effective, but costly technologies or drugs. Conversely, eliminating overuse or misuse of therapies or diagnostic tests can lead to both reduced costs and improved outcomes.

The balanced pursuit of the Triple Aim is unfortunately not congruent with the current business models of any but a small number of healthcare organizations. Payment dynamics often lead hospitals to focus only on care within their walls, viewing readmissions for chronic diseases such as congestive heart failure as the result of defects outside the hospital and not as their responsibility to avert (Bisognano and Kenney 2012). For hospitals paid based on number of patients treated, averting readmission incurs costs from additional effort such as patient education and post-discharge follow-up (which may not be reimbursed as these occur outside the hospital) and reduces revenue by decreasing the number of patients being admitted. In such instances, rational common interests and rational individual interests are in conflict. Lack of system knowledge among clinicians and organizations leads them to optimize the components of the system with which they are most familiar, at the expense of the whole.

Movement between the various care levels (primary, secondary, tertiary, and community care) typically involves passage across an interface that is governed by rules of varying degrees of formality. Examples include referral to hospital by a primary care physician or discharge from an acute hospital to a long-stay facility. However,

these movements are often not seamless, thus hampering efforts to enable patients to be treated in the most cost-effective settings.

The pursuit of the Triple Aim requires health services to move from the current silo-based approach to a more systematic and integrated model of care. Integrated care brings together inputs, delivery, management and organization of services related to diagnosis, treatment, care, rehabilitation, and health promotion as a means to improve the services in relation to access, quality, user satisfaction, and efficiency (Gröne and Garcia-Barbero 2001).

Measurement drives behaviour. As such, the move towards better integration of care has been accompanied by efforts to measure health status rather than just healthcare. The proposed framework shown in Fig. 11.7.1 (Arah et al. 2006) illustrates a measurement system that takes into account non-healthcare determinants of health, health system performance across the various care sectors, and embeds healthcare within the broader economic, social, and political context of a country. A framework that is unduly narrow and clinical in its focus will miss this big-picture perspective.

Patient engagement and empowerment

Very few healthcare-delivery models currently view the patient as a resource who can help improve healthcare delivery for themselves and each other. Patients are either viewed as liabilities who consume scarce resources, or as passive vessels into which treatments are poured (Dzau et al. 2012). At times, healthcare services not only fail to take advantage of the patient's capabilities, they also diminish them: studies have shown that during hospitalization, older people actually lose the ability to function independently (Creditor 1993; Sager et al. 1996).

Patients with chronic diseases can profoundly change the development and progression of their conditions through effective self-care, goal-setting, and adherence to prescribed medication, exercise, and nutrition regimes. A survey by the Commonwealth Fund (Schoen et al. 2011), however, suggests that this opportunity is being lost in many healthcare systems, owing to the professionals' failure to prepare patients for this role by discussing treatment goals/priorities, making treatment plans that patients can carry out in daily life, and giving clear instructions on symptoms and when to seek care.

On the other hand, we have the positive example in Jönköping, Sweden, where patients with kidney failure have been trained to use hospital dialysis machines themselves, thereby improving the efficiency, productivity, convenience, and safety of care delivery. These patients have also been empowered to provide advice to one another on ways of managing their illness (Dzau et al. 2012).

Several important issues need to be addressed in increasing patient participation in healthcare systems (Saltman and Figueras 1997). One is whether choice is equally important in all healthcare decisions. Another is, given the special characteristics of healthcare, do users have access to enough information and are they able to understand it sufficiently to make an informed choice? Several countries have sought to inform the public by means of publication of rankings of outcomes by hospital or physician. However, these are subject to substantial methodological limitations and also provide scope for opportunistic behaviour by providers, either to exclude patients with higher risks or to manipulate the data that are presented. Finally, enhancing choice risks increasing health inequalities as those with most resources (time, money

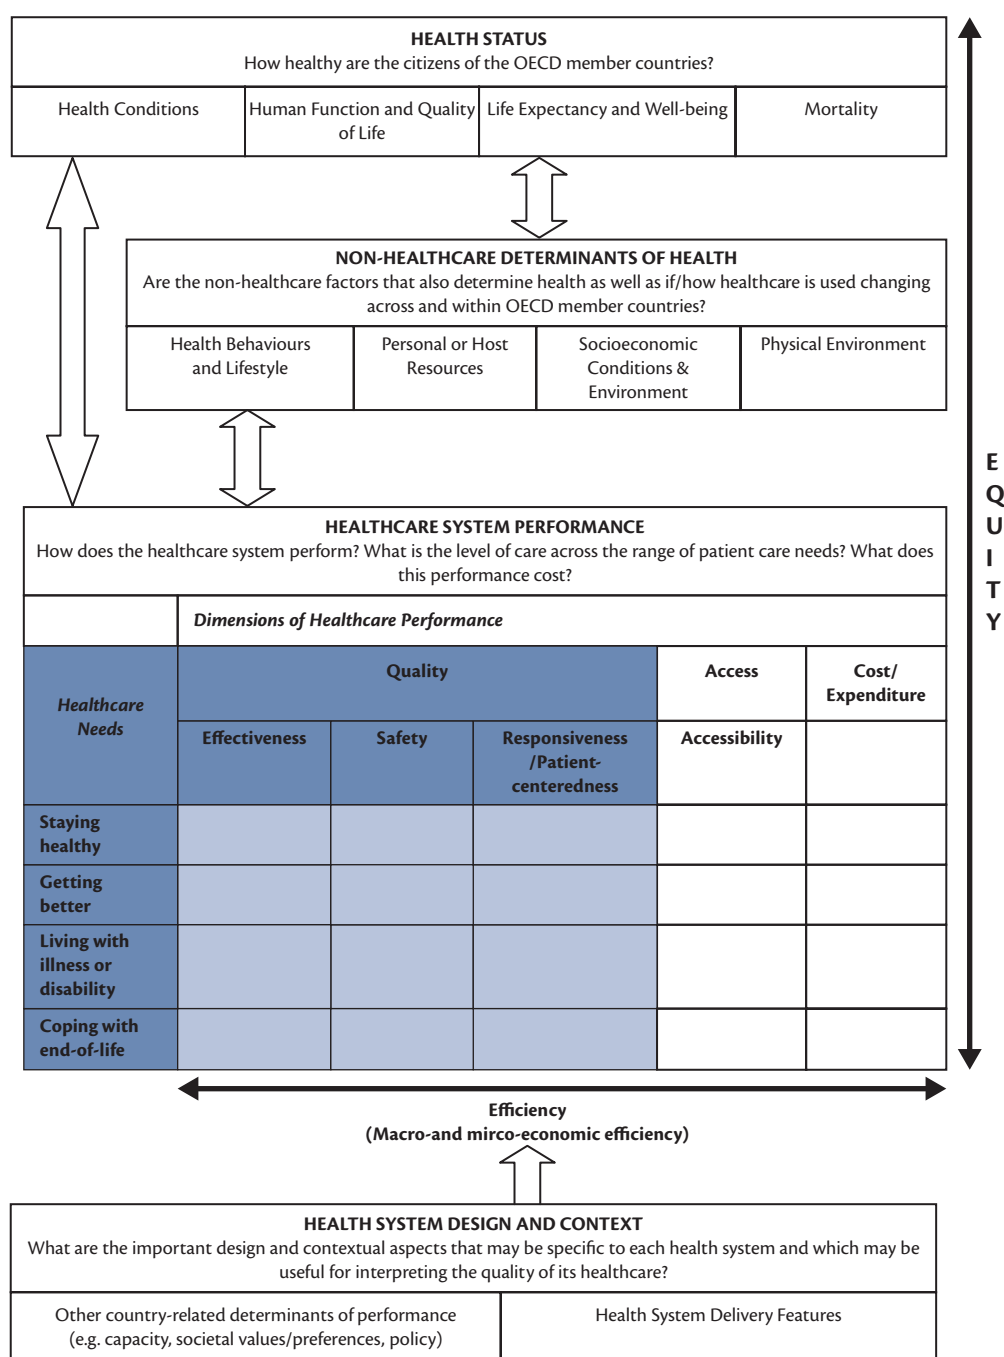

Fig. 11.7.1 Conceptual framework for OECD Health Care Quality Indicator (HCQI) Project.

Reproduced from Arah, O.A. et al., A conceptual framework for the OECD Health Care Quality Indicators Project, *International Journal for Quality in Health Care*, Volume 18, Issue Supplement 1, pp. 5–13, Copyright © 2006 International Society for Quality in Health Care and Oxford University Press, by permission of Oxford University Press.

and energy) are likely to have the greatest opportunity to make choices.

Cost sharing

Increasingly, the debate about healthcare costs is no longer about ‘who pays?’ but about the optimal formula for cost sharing, bearing in mind the need to balance efficiency goals against equity concerns (Lim 2004). Proponents of this approach argue that there is ‘no free lunch’. Health insurance premiums have to be paid by

the insured, employee medical benefits form part of wage costs, and public expenditures on healthcare are ultimately paid for by taxpayers. The key question is how best to structure the healthcare system, and the means of financing it, in order to keep it efficient, while making it accessible to all at rates that are affordable to them (Ministry of Health 1993).

People with the most control over what drugs get prescribed and what procedures get done have little incentive to lower these costs (indeed, to the extent that they get paid for the procedure, their

incentives are often quite the opposite). Furthermore in a fee for service system, it is not in the economic interest of doctors and hospitals to put themselves out of business by promoting disease prevention. Likewise, patients often feel little need to control the costs of their own medical care if it is fully covered by insurance or the state. These approaches fuel overconsumption of healthcare services, hence contributing to rising healthcare costs. Some healthcare systems have thus tried to structure their financing system to give the individual maximum incentive to stay healthy, save for his or her medical expenses, and avoid using more medical services than is absolutely required.

Cost sharing for health services can help limit overconsumption of healthcare and could instil greater personal responsibility for health. On the other hand, cost sharing (or patient co-payment) can and has led to access and equity problems in some countries. Hence, cost sharing or co-payment should be one component of a multifaceted, multilayered healthcare financing system (Lim 2004). It is important to achieve an appropriate balance between personal responsibility with sufficient incentives for people to be prudent and to look after their own health, and risk pooling to provide a comprehensive safety net should they fall sick.

Cost sharing also allows governments to target their social spending more carefully. For example, greater subsidies could be directed at financially needier patients through financial means-testing. Social provision should be about protecting the poor more than subsidizing the rich. At the same time, in fast-ageing societies, especially, increased expenditures on the elderly must not squeeze out healthcare investments in the young (*The Economist* 2012).

These emerging themes bring new opportunities for public health practitioners to reorient health services towards the maximization of health gains. The next section will explore strategies for health services to translate these opportunities into reality.

Strategies for health services

In devising strategies for health services, we need to take into account the complex nature of healthcare where reductionist, mechanical, and linear methods of problem-solving tend to flounder against the laws of unforeseen consequences and incomplete information. It is also important to differentiate the means from the ends. For example, while healthcare systems aim for universal coverage to ensure that no one is denied healthcare that they need because of inability to pay, the means they have employed to achieve this can markedly differ.

Another consideration in developing strategies for health services is the mismatch between the lifecycles of different elements in the healthcare system such as major infrastructure (e.g. hospitals), technological advances (including information technology), service models, and government/regulatory policies. This can pose a major problem for planning and coordination, in particular to ensure alignment and timeliness in response to a constantly changing environment.

It is impossible in the space available to provide a comprehensive overview of every strategy that might be employed to enhance health services. Instead, this section focuses on key steps in the strategic planning process for health services where public health professionals have a potentially vital role to play. It starts by looking at the needs assessment and priority setting process to ensure that the health services provided reflect the health needs of the population that they serve. Following that, it reviews the design and organization of health services to enhance the efficiency with which services are delivered. It concludes by discussing the enablers that are necessary to implement, sustain, and enhance these services.

Needs assessment and priority setting

‘Need’ may best be defined as the ability to benefit from ‘healthcare’, which depends both on morbidity and on the effectiveness of care. Need should not be confused with supply or demand. The relationship between need and demand is mediated by differing illness behaviours. Demand is what people would be willing to pay for in a market or might wish to use in a system of free healthcare, and supply is what is actually provided. It is misleading to measure existing service provision as though it were an indicator for need. Similarly, the measurement of waiting lists, reflecting as they do demand mediated by doctor as agent, is also misleading (Stevens and Gabbay 1991).

Healthcare needs are those that can benefit from healthcare (health education, disease prevention, diagnosis, treatment, rehabilitation, terminal care). Health needs incorporate the wider social and environmental determinants of health, such as deprivation, housing, diet, education, and employment. This wider definition allows us to look beyond the confines of the medical model based on health services, to the wider influences on health. Health needs of a population will be constantly changing, and many will not be amenable to medical intervention (Wright et al. 1998).

Fig. 11.7.2 illustrates how need, demand, and supply might overlap or differ. It shows seven fields of services divided into (E) those

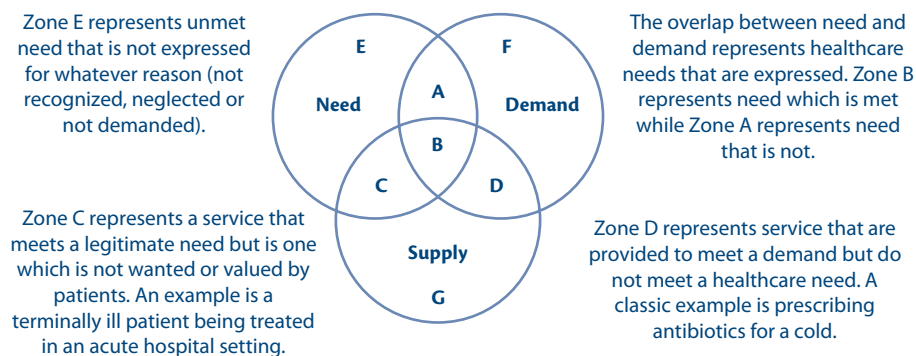

Fig. 11.7.2 Need, demand, and supply of healthcare.

for which there is a need but no demand and supply, (F) those for which there is a demand but no need or supply, (G) those for which there is a supply but no need or demand, and then (A–D) the various degrees of overlap (NHS Confederation 2008).

The key challenge is to make the three circles of need, demand, and supply more congruent. This includes demand management and changing supply as well as better definition of need. Demand management may involve curtailing it where it is inappropriate (areas F and D in Fig. 11.7.2) or stimulating it (areas A and B). Varied mechanisms through which demand can be influenced include: the accessibility and organization of services, the provision of health information, education, and financial incentives. Demand can also be induced by supply: geographical variation in hospital admission rates is explained more by the supply of hospital beds than by indicators of mortality (Feldstein 1964); referral rates of general practitioners owe more to the characteristics of individual doctors than to the health of their populations (Wilkin 1992).

Strategies that act on supply of health services include reducing the number of healthcare professionals or facilities, setting global budgets for providers (Schwartz et al. 1996), giving professionals incentives to reduce the amount of care provided, and reducing access to care (Abel-Smith et al. 1995). Even need can be shifted somewhat, with new findings on disease pathology and new treatments that are effective.

Distinguishing between individual needs and the wider needs of the community is important in the planning and provision of local health services. Without a proper need assessment process, the pattern of health services will frequently reflect only what a few people perceive to be the needs of the population rather than what they actually are and often those whose needs are greatest will receive the least (Hart 1971).

Assessment of health needs is a systematic method of identifying unmet health and healthcare needs of a population and making changes to meet these unmet needs (Wright et al. 1998). The principal activities involved in healthcare needs assessment are the assessment of incidence and prevalence (how many people need the service/intervention), the effectiveness and cost-effectiveness of services (do they confer any benefit, and if so at what cost, i.e. what is the relative benefit?) and baseline services. Changing the provision of healthcare services for the better necessitates knowledge of existing services, both to know which services ought to change and to identify opportunities for the release of resources to enable the change to happen.

Health needs assessment should not just measure ill health, as this assumes that something can be done to tackle it. It should incorporate the concept of a capacity to benefit which requires an assessment of the effectiveness of health interventions and attempts to make explicit what benefits are being pursued, at the level of individuals and the population.

Health needs assessment should include two other objectives. Firstly to improve the spatial allocation of resources so that broadly equal populations receive broadly equal resources. Secondly the accurate targeting of resources so that those who get a service need it, and those who need a service get it.

As the capacity to benefit is always going to be greater than available resources, health needs assessment should also incorporate questions of priority setting (Donaldson and Mooney 1991). Some commentators have argued that rationing should not be necessary if

either sufficient funding was made available, typically by redirecting it from other areas of public expenditure or raising taxes, or by ensuring that available resources are used more efficiently.

In reality, some form of rationing has always taken place in all healthcare systems although, in most cases, this was implicit, inextricably linked to clinical judgement. Priority setting or rationing in healthcare continues to be a politically charged topic, but recently its necessity has gained wider recognition as it is impossible to provide everyone with every effective intervention they might need or want (Sabik and Lie 2008). Explicitly addressing priority setting is necessary to develop fairer methods to allocate scarce healthcare resources (Fleck 1994) through a transparent process that balances clinical, ethical, and economic considerations (Black 1994).

Priority-setting approaches can be broadly grouped into two categories: outlining principles and defining practices. Countries such as Norway, the Netherlands, Sweden, and Denmark decided to develop principles that would guide prioritization efforts. In the Netherlands, the Dunning Committee (Committee on Choices in Health Care 1992) proposed four criteria that any intervention to be funded from social insurance should meet: necessity, effectiveness, efficiency, and individual responsibility. They described these principles as forming a sieve for sifting out services that should not be publicly funded ('Dunning's funnel'). The idea was that one should apply these successively beginning with the principle of necessity, and then limiting the number of services provided. The Committee excluded services that could easily be paid for by the individuals themselves. One example the committee gave was routine adult dental care. Although such dental care is necessary, effective, and efficient, adults can easily pay for such services out of pocket, and it is therefore best left to an individual's responsibility. The drawback of this approach is that because of their abstractness, government commissions that outlined principles have had little direct impact on their countries' policies.

Other countries, such as the United Kingdom, Israel, New Zealand, and the state of Oregon in the United States established bodies that would actually recommend what services should be provided within the system. Decisions may lead to blanket exclusions of interventions or of condition–intervention combinations, as in the approach taken in Oregon, or production of guidelines, as has been done in New Zealand (The National Advisory Committee on Health and Disability) and by the National Institute of Health and Care Excellence in the United Kingdom. The experience of Oregon has been especially interesting because of the technical and ethical issues it has raised. It was designed to create a list of condition–intervention pairs, ranked on the basis of cost–benefit, with a cut-off point based on available resources below which combinations would not be funded. This initial method was, however, abandoned because of a public outcry over the resulting ranking of services, for example: appendectomy was rated lower than cosmetic dentistry. In response to this public reaction as well as criticism of the methodology, the Commission set out to rank healthcare services based on more broadly defined criteria, where expert knowledge and intuitive judgements by the Commissioners about appropriateness played a much larger role. The process also raised important ethical questions as the exercise was confined to poor women and children in the Medicaid programme and services denied to them would remain available to others (Rosenbaum 1992).

In the United Kingdom, the National Institute for Clinical Excellence (now the National Institute for Health and Care Excellence (NICE)) was established in 1999 to: appraise new health technologies, develop clinical guidelines, and assess interventional procedures (Rawlins 1999). In conducting these activities, NICE addresses questions including what constitutes necessary and appropriate care, how to incorporate cost-effectiveness considerations, and what interventions should be publicly funded.

The challenge of healthcare prioritization is to identify an appropriate balance between an expert-led process and a process that emphasizes public involvement in decision-making to ensure that decisions reached are legitimate. Ultimately, while public health professionals have an important role in providing the evidence on which any debate on priority setting must be based, priority setting in a publicly funded system is the responsibility of politicians. Decision-making inevitably involves trade-offs between objectives as a balance is sought among universal coverage, comprehensiveness of services, equity, efficiency, cost containment, and broader social values (Sabik and Lie 2008).

Design and organization of health services to ensure efficient service delivery

Conventional service delivery is often based on institutional hospital care and a supply of trained health professionals—all relatively expensive with inpatient care typically consuming 45–75 per cent of resources dedicated to healthcare (Saltman and Figueras 1997). Moreover, different professionals often work in organizational silos, and fail to integrate services to achieve best value and best care. New technologies in fields such as genetics, imaging, miniaturization, pharmaceuticals, and information are changing the mix of preventive, diagnostic, and treatment practices, enabling services to be delivered less expensively to wider populations in their own homes or communities instead of hospitals.

Health systems have adopted several strategies to meet these challenges. They include organizing the network of hospital services to achieve a more efficient and effective configuration through decentralization and centralization initiatives (see ‘Reorganizing the system: decentralization, recentralization, and privatization’). Three other strategies are described in the following subsections: improved targeting of interventions, substitution, and integration of services in the hospital and community.

Improved targeting of interventions

Bohmer (2011) identified specification and planning as a common habit of high-value healthcare organization. These organizations specify decisions and activities in advance. Whenever possible, both operational decisions, such as those related to patient flow (admission, discharge, and transfer criteria), and core clinical decisions, such as diagnosis, tests, or treatment selection, are based on explicit criteria. Criteria-based decision-making is manifested in the use of clinical decision support systems and treatment algorithms, severity and risk scores, criteria for initiating a call to a rapid-response team, or triggering the commitment of a future resource (e.g. a discharge planner, pre-procedure checklists, and standardized patient assessments). Specification also applies to separating heterogeneous patient populations into clinically meaningful subgroups—by disease subtype, severity, or risk of complications—each with its own distinct pathway. For example, genomic testing has allowed oncology units to divide

patients into separate groups according to their probable response to specific therapies (for instance, Kirsten RNA-associated rat sarcoma 2 virus (*KRAS*) gene testing for cetuximab therapy). And at Intermountain Healthcare in Utah and Idaho, the needs of psychiatric patients are divided into mild (routine care by a primary care physician), moderate (team care), and severe (specialist referral), using a scoring system based on published guidelines (Rathod et al. 2010).

To promote such standardization, we need to accelerate the healthcare evidence base and support the rapid sharing of clinical protocols, best practices, and outcomes data. There is concurrently a need to make effective use of information technologies to automate clinical information and make it readily accessible to patients and all members of the care team (IOM 2001). Excellent information infrastructure and well-thought out and implemented modes of ongoing communication can reduce the need to craft laborious, case-by-case strategies for coordinating patient care.

A second common characteristic of high value organizations is infrastructure design. They deliberately design microsystems (Nelson et al. 2011)—including staff, information and clinical technology, physical space, business processes, and policies and procedures that support patient care—to match their defined subpopulations and pathways. Thus, different conditions or patient groups have different microsystem designs. The various tasks of care are allocated to different members of a clinical team (including the patient), with the skills and training of each staff member matched to the work.

Substitution

Substitution refers to the process of regrouping resources (staff, equipment, information, facilities, etc.) across and within care settings to exploit the best and least costly solutions to achieve better clinical, financial, and patient-related outcomes. A useful typology differentiates substitution into three categories: moving the location at which care is delivered, introducing new technologies, and changing the mix of staff and skills. There may be other substitution types according to different combinations of these three (Warner 1996). For example, moving care from the hospital to community based care may involve:

- ◆ Location only such as for physiotherapy.
- ◆ Location and technology such as for point-of-care laboratory testing and telemedicine that allows remote consultations.
- ◆ Location and staff and/or skills such as nurse-led home care.
- ◆ All substitution types such as home dialysis services.

In addition to substitution, the weightage of services across the spectrum of care is also changing with greater emphasis being placed on prevention and self-management to reduce the demand for care. Prevention programmes have historically focused on younger or working-age adults, but there is increasing recognition of the value of prevention programmes aimed at older people with services focused on increasing functionality. These health promotion and primary prevention strategies should ultimately reduce the total demand for healthcare services and healthcare costs. However, the difficulties in measuring health promotion in terms of cost-effectiveness so that it can be compared with other health services interventions, has meant that health promotion’s role

has tended to be undervalued. Public health professionals have to develop more and better ways to evaluate health promotion that satisfy the needs of policymakers, managers, and clinicians so the full potential of health promotion can be realized (McKee and Bojan 1998).

Health services should be reoriented from a hospital-centric model to a model with primary healthcare at the core of the healthcare system, and secondary and tertiary care serving as supporting, referral levels. Healthcare systems configured around primary care produce healthier populations at lower cost. In the United States, for example, overall health is better in regions with more primary care physicians and where primary care functions well. By contrast, overall health is worse where specialists predominate (Starfield et al. 2005). An effective primary care system has the following virtues (Oldham 2012):

- ♦ It can coordinate the care of the many people with multiple, complex health needs, in a way that individual specialists cannot.
- ♦ It can deliver care closer to people, increasing convenience, especially in areas remote from hospitals.
- ♦ As a first point of contact for patients it facilitates the early detection of illness, and thereby improves outcomes.

In addition to substitution within healthcare, substitution should also occur between healthcare and other sectors, recognizing the importance of lifestyle and social determinants in improving health outcomes. For example, the ‘actual’ causes of mortality in the United States and other developed countries include behaviour such as smoking, violence, physical inactivity, poor nutrition, and unsafe choices (McGinnis and Foege 1993). The health and social sectors in some countries are thus pooling resources particularly in the provision of services to the elderly to tackle social isolation, engage communities more widely, adapt or develop homes, and make cities more age-friendly places.

Integration of care

The involvement of increasingly more parties in the delivery of healthcare accentuates the need to adopt a systems perspective to foster evolution of care delivery as a whole rather than focusing on single elements. Care processes need to be redesigned to enable coordinated, seamless care across patient conditions, disciplines/specialties, settings and clinicians, and over time. The key challenge is to match evidence-based, appropriate, and responsive care to patients according to their needs (such as various chronic diseases) across the various stages of their life. Capital investments and operating expenses should encourage thinking across boundaries. As an illustration, questions to be asked might include, ‘Might two additional home outreach nurses be better for heart failure patients than another cardiologist?’ (Berwick 2008).

One way of achieving this is by designing distinct integrated care platforms (Leape 2009) for conditions that share common work and support requirements, such as chronic disease care, complex acute care, palliative, and end of-life care. Every care platform must have the following characteristics:

- ♦ Patient centredness: personnel, facilities, and services are organized to meet all patients’ needs efficiently and responsively; to be available when and where needed, and to include the patient and family as partners in care.
- ♦ Work assignment: work is assigned to the individuals who are responsible for its completion. Assignments strive to maximize the performance capability of each individual while ensuring that work is done by the least expensive qualified caregiver or multidisciplinary team at the location most accessible to the patient. The physician participates when his/her special expertise is required and when patient expectations permit no alternative.
- ♦ Support: the support framework—people, systems, and tools (e.g. technologies, IT, telecommunications)—is defined by the work and patient participation.
- ♦ Community linkage: linkages to community advocacy, support, and education groups (especially health literacy) are incorporated into the design as appropriate (e.g. for patients with chronic conditions).
- ♦ Variation management: ensuring quality and efficiency requires determining whether variations in process are appropriate. Process and outcome measures should thus be incorporated into daily work. Use of such measures makes it possible to understand the degree to which performance is consistent with best practices, and the extent to which patients are being helped. Exception analysis assesses whether variations result from: (1) adaptations to a specific patient requirement, (2) evolution of new evidence (good), (3) lack of training in appropriate care, or (4) poorly defined care pathways (bad).
- ♦ Transparency: the results of the delivery process and outcomes of care should be shared with all concerned, including patients. This would enable patients, caregivers, organizations, and managers to know the ‘state of the system’ with respect to its reliability, adherence to evidence, cost, and progress in improvement.

For the integrated platform to work we need an ‘integrator’ which accepts responsibility for the Triple Aim of improving the patient experience of care, improving the health of populations, and reducing the per capita cost of healthcare for a specified population. The simplest such form, such as Kaiser Permanente, has fully integrated financing and either full ownership of or exclusive relationships with delivery structures which enables it to use those structures to good advantage. A unified financing or a single delivery system is not, however, necessarily a prerequisite for an integrator. That role might be within the reach of a powerful, visionary insurer; a large primary care group in partnership with payers; or a regional health system that will link healthcare organizations (as well as public health and social service organizations) whose missions overlap across the spectrum of delivery (Berwick 2008). At the patient level, the integrator ensures that members of the population, especially those with chronic illnesses, have someone who can work with them to establish a plan for their ongoing care, guide them through the jungle of health services, and be their advocate.

The integrator has to segment the population according to need such as health status, level of support from family or others, and socioeconomic status, to facilitate efficient and equitable resource allocation (Lynn et al. 2007). In most cases, the integrator would not be a direct provider of all necessary services. Instead, it would need to commission some services from suppliers through business relationships consciously designed to facilitate pursuit of the desired outcomes.

Enablers

Three key enablers are needed to translate strategies into reality: intelligent purchasing, a workforce with the appropriate capacity and capability, and a robust information and knowledge management system.

Intelligent purchasing

All health systems exercise some form of purchasing but the prevailing approach to paying for healthcare, based predominantly on individual services and products, encourages wasteful and ineffective care (IOM 2012). Payment systems that are based on workload tend to disincentivize providers from coordinating care for patients across settings and over time as the benefits of investments (and cost) made by one group of providers are realized by a different group of providers. For example, investments in primary care preventative efforts tend to reduce demand for hospital services rather than primary care services. Hospitals may not be keen on these systems-level savings since their own reimbursement may decline with the decreased workload.

Health systems need to move from passive forms of purchasing—the mere reimbursement of providers—to more proactive and strategic forms of purchasing that consider which interventions should be purchased, how they should be purchased and from whom (Figueras 2005). In an increasing number of countries intelligent purchasing is seen as an alternative to a traditional command-and-control approach to implement health policy objectives, including as a means of reorienting the focus of health services, to ensure that they reflect health needs and provide cost-effective care. Its essential characteristic is that it separates purchasers from providers but binds each party by means of contracts to explicit commitments, with creation of the economic motivation to fulfil these commitments (McKee and Figueras 2009).

Payers/purchasers should adopt outcome- and value-oriented payment models where payment systems align financial incentives with the implementation of care processes based on best practices and the achievement of better patient outcomes. Payment systems should also reduce fragmentation of care by supporting high-quality, team-based care focused on patients' needs. Contracts can be used to develop intersectoral responses to health problems and to reorient healthcare providers so that they integrate prevention with curative care.

Contracts should also provide an opportunity for providers to share in the benefits of quality improvement. Substantial improvements in quality are most likely to be obtained when providers are highly motivated and rewarded for carefully designing and fine-tuning care processes to achieve increasingly higher levels of quality and safety. Rewards should thus be located close to the level at which the reengineering and process redesign needed to improve quality are likely to take place (IOM 2001).

Purchasers represent the interests of their populations, in particular the vulnerable and disadvantaged groups as well as underserved communities, by allocating resources and purchasing services in accordance with their needs. There is, however, a need to guard against the risk of providers underemphasizing or phasing out services that are less profitable. Contracts should thus provide fair payment for good clinical management of the types of patients seen. Clinicians should be adequately compensated for taking good care of all types of patients, neither gaining nor losing

financially for caring for sicker patients or those with more complicated conditions. The risk of random incidence of disease in the population should reside with a larger risk pool, whether that is large groups of providers, health plans, or insurance companies (IOM 2001).

Purchasing also offers a means for enhancing participation by the population in the organization of healthcare by providing the opportunity for consumers and purchasers to recognize quality differences in healthcare and direct their decisions accordingly. To do this, consumers need to have good information on quality and the ability to use that information as they see fit to meet their needs.

Implementation of an intelligent purchasing system is a complex process requiring a high level of skills and well-developed information systems. At a minimum, information is required on patient flow, cost, and utilization across specialties or diagnostic groups and demographic and risk groups. Purchasing decisions also need to take into account the reality that medical care is extremely complex. Diagnostic labels are often imprecise and clouded by a degree of legitimate uncertainty. Decisions on clinical management also incorporate values and beliefs relating to factors such as attitude to risk and the utility placed on different health states. It is thus important that expectations of what can be achieved are realistic (McKee and Clarke 1995). Contracts must incorporate sufficient flexibility and reflect the views of all those concerned if they are to retain any credibility. It should also be recognized that purchasing may not be the best option for some services especially where clear specifications in terms of the desired product/service cannot be defined clearly.

While the focus of purchasing should ideally be on outcomes, outcomes are typically more difficult to measure and may only become apparent long after the intervention took place. Some outcomes may also be rare and the sample size required to detect a deviation from what is expected may be very large. For example, Mant and Hicks (1995) have shown, on the basis of knowledge of effective treatment for myocardial infarction, that, in a comparison of two typical hospitals, it would take 73 years of data to detect a significant 3 per cent reduction in mortality whereas the corresponding difference in process measures, relating to uptake of treatments, would emerge after only 4 months. Where process or structure measures are used there should be evidence that they correlate with a good outcome. Measures based on structure can be of some value, based on the assumption that high-quality care cannot be provided in the absence of basic prerequisites, such as adequately trained staff, but this is a necessary rather than a sufficient measure and should normally be supplemented by measures of either process or outcome.

All these activities (e.g. needs assessment, performance analysis, negotiating, and monitoring) incur transaction costs. A substantial increase in quality and efficiency is required to justify these additional costs. Increasingly, purchasers and providers are entering into long-term contractual relationships that reduce transaction costs (Rosen and McKee 1995). If transaction costs can be minimized without compromising the pursuit of the objectives of equity and health gain, intelligent purchasing can provide a formidable instrument to promote population health.

Workforce

A major challenge in transitioning to the desired models of care described previously is preparing the workforce to acquire new

skills and adopt new ways of relating to patients and each other. At least three approaches can be taken to support the workforce in this transition:

- ◆ *Redesign the way health professionals are trained.* Healthcare professionals should be taught evidence-based practice and equipped with the skills and tools to access and apply the expanding knowledge base. They should also have sufficient communication and behavioural skills to work effectively with patients, not least in helping to promote treatment adherence and health-enhancing lifestyle changes. In addition they need to acquire the skills to improve the processes and systems of care through proven methods and actions. Furthermore as effective health services will increasingly be delivered by collaborative teams of clinicians, with each member playing a vital role, the training should adopt a multidisciplinary approach and continually advance the effectiveness of teams instead of training health professionals purely by discipline. As almost every country wants more patients to be treated in the community rather than in hospitals, we need to ensure that healthcare professionals spend considerable time during training in the community, not just in hospitals. We also need to review the necessity for the expensive additional years of education for an increasing number of doctors and nurses to be trained in very narrow subspecialties (Emanuel and Fuchs 2012) and its alignment with the wider interests and needs of the population.
- ◆ *Modify the ways in which health professionals are regulated.* Regulation of healthcare professionals is designed to protect the public and ensure that patients are kept safe, but providing such protection needs to be balanced against the regulatory burden and the need to retain sufficient freedom for innovators to succeed. Regulation should be focused on the patient and should be independent of professional interests. Scope-of-practice laws and other workforce regulations need to allow for innovation in the use of all types of clinicians to meet patient needs in the most effective and efficient way possible. Statutory regulation should be used to protect the public in areas of high risk, but other processes should be used when the risk is low. Ongoing licensure and certification requirements should also reflect the need for lifelong learning and evaluation of competencies to ensure that healthcare professionals have the specific skills for the time and contexts in which they work (Dzau et al. 2012).
- ◆ *Examine how the liability system can constructively support changes in care delivery while remaining part of an overall approach to accountability for healthcare professionals and organizations.*

In addition to the professional workforce, it is also important to work on securing the supply of informal care. Care provided by families is the backbone of long-term care. But it is difficult to maintain or increase it in the face of falling support ratios, urbanization and migration, and changing work patterns. One option is to direct cash and services to support carers. Another is to use technological innovations to provide information and support. Governments can also innovatively incentivize or reinforce traditional family caring responsibilities through the tax system and other regulatory measures (Hope et al. 2012).

Information and knowledge management

The knowledge of how to configure structures and processes to attain the best possible clinical outcomes will become one of the

Table 11.7.1 Characteristics of a continuously learning healthcare system

Science and informatics <i>Real-time access to knowledge</i> —a learning healthcare system continuously and reliably captures, curates, and delivers the best available evidence to guide, support, tailor, and improve clinical decision-making and care safety and quality. <i>Digital capture of the care experience</i> —a learning healthcare system captures the care experience on digital platforms for real-time generation and application of knowledge for care improvement.
Patient–clinician partnerships <i>Engaged, empowered patients</i> —a learning healthcare system is anchored on patient needs and perspectives and promotes the inclusion of patients, families, and other caregivers as vital members of the continuously learning care team.
Incentives <i>Incentives aligned for value</i> —in a learning healthcare system, incentives are actively aligned to encourage continuous improvement, identify and reduce waste, and reward high-value care. <i>Full transparency</i> —a learning healthcare system systematically monitors the safety, quality, processes, prices, costs, and outcomes of care, and makes information available for care improvement and informed choices and decision-making by clinicians, patients and their families.
Culture <i>Leadership-instilled culture of learning</i> —a learning healthcare system is stewarded by leadership committed to a culture of teamwork, collaboration, and adaptability in support of continuous learning as a core aim. <i>Supportive system competencies</i> —in a learning healthcare system, complex care operations and processes are constantly refined through ongoing team training and skill building, systems analysis and information development, and creation of the feedback loops for continuous learning and system improvement.

health service’s most important assets. Healthcare organizations must thus create, maintain, and disseminate the institutional knowledge required to realize good outcomes.

As healthcare is complex and constantly changing, we need to build healthcare systems that continually learn, in real time and with new tools, how to better manage problems. Data generated in healthcare delivery—whether clinical, delivery process, or financial—should be collected in digital formats, compiled, and protected as resources for managing care, capturing results, improving processes, strengthening public health, and generating new insights. Decision support tools and knowledge management systems can be included routinely in healthcare delivery to ensure that decisions are informed by the best evidence. The characteristics of a continuous learning healthcare system are summarized in Table 11.7.1 (IOM 2012).

Regulators have a key role in facilitating this learning process by clarifying and improving rules governing the collection and use of clinical data to safeguard patient privacy while promoting the seamless use of such data for better care coordination and management, improved care, and enhanced knowledge. Legal protections should be put in place to shield individuals from improper use of de-anonymized health data and educational campaigns

should be conducted, aimed at providers and public alike, to raise awareness of the rights, responsibilities, risks and benefits related to health data.

Conclusion

Health services have an important role to play in improving the health status of populations. This chapter has identified mechanisms through which public health can play a major role in maximizing the health gain obtained from health services, in particular in the design of systems that ensure that patients are managed at the level of the healthcare system that is most appropriate, the creation of mechanisms that identify and promote high-quality clinical care, and the reorientation of curative services towards prevention.

Public health professionals, with their emphasis on improving population health, have a key role in ensuring that the pursuit of health gain becomes a central objective of healthcare services, whatever other objectives are being pursued by others (McKee and Figueras 2009). To do so, they must promote the equitable use of interventions that are effective and appropriate for the population in question, reduce interventions that are ineffective or harmful, and maximize the health gains obtained with the available funding. Much will depend on the ability of the public health profession to adapt and bring its portfolio of tools and skills to bear on rapidly changing health services.

Training of public health professionals in developing countries

Vonthanak Saphonn, San Hone,
and Roger Detels

Introduction to training of public health professionals in developing countries

Public health and medical structures, systems, and training are essential for the health of a country (Heller et al. 2007; Bangdiwala et al. 2010). This is particularly true for developing countries, which have great disparities in wealth and limited funds to invest in the health of their citizens. In developing countries, as well as in developed countries, public health services and medical resources must be made available at the national, provincial, sub-provincial, and local district levels. The skills and requirements of public health and medical professionals at each of these levels differ and are unique within each level. The mandate of public health is broad, and therefore requires some level of specialization within the profession. Thus, various public health professionals are responsible for assuring access to healthcare, maternal/child health services, protection of the environment, including provision of adequate and safe levels of water and safe disposal of human and other waste, implementation of community health programmes such as immunization coverage, prevention and control of endemic and epidemic health threats from microbial agencies, addressing the current chronic disease epidemic, and administration/management of the broad and diverse public health workforce at each level. Thus, public health training requires providing training not only in medical sciences, but also in technical fields such as microbiology, chemistry and the physical sciences, management sciences and behavioural, social, and political sciences, statistics, epidemiology, and research methodologies.

The public health workforce draws individuals from a variety of backgrounds relevant to their intended public health role, including medicine, nursing, and the behavioural, management, and biological/physical sciences (Beaglehole and Dal Poz 2003). Generally, health training programmes provide training at the certificate level primarily for health professionals and others serving at the local level, which may include health volunteers (who are the core of many health systems and provide service at the village level), specialized training (e.g. nurse midwife), as well as training

at the master's level (usually requiring 1–3 years of graduate study) and the doctoral level (requiring 4–6 years of graduate study) for those who become leaders of public programmes and researchers. Training at the graduate level also includes specialized training in specific fields for those who focus on environmental, social, and healthcare aspects of public health, as well as in the broad mandate of public health. Although most public health training programmes provide basic initial training in public health, there is also an important need to provide postgraduate and refresher training to ensure that the public health workforce continues to utilize the most modern strategies and resources.

In the opinion of some public health professionals, including the authors, there is too often a mismatch between the role and responsibilities of public health professionals at each level and the training that they receive. Too often, public health curricula in developing countries were developed by the European colonialists based on the European system, and do not adequately address current health problems of the country. This mismatch reflects both the content of the training programmes and the strategies/content of the country's public health system itself. Public health planners, managers, and administrators are confronted by a range of barriers to achieving optimal public health, including funding constraints, politics, and the scarcity of qualified personnel and public health leaders. It is the responsibility of public health trainers to develop strategies and curricula to overcome these barriers and to ensure that the training of public health professionals is appropriate and has the flexibility to provide trainees with the ability to devise new strategies to address constantly changing public health issues and problems. In some instances, this requires reconsideration of the current public health structure to ensure maximum effectiveness. Public health programmes need to ensure that health professionals in training see a clear career path for themselves, that there is an optimal distribution of health professionals, particularly to rural and remote areas, and that the system provides both monetary and non-monetary incentives to motivate them. In this chapter, we address each of these issues in greater depth and make suggestions for improvement and enhancement of health training in developing countries.

Typical public health structures in developing countries—health system structure in developing countries

Typically, government health systems in developing countries have a tiered system for providing health, comprising the national, provincial, sub-provincial, and local levels. In addition, in most developing countries there is also a private health-care system which provides services primarily to the wealthy. Further non-governmental and national and international organizations may provide clinical services. Sometimes these operate outside the purview of the government-sponsored public health system which can create problems. In this chapter we will focus on training relevant for the government-sponsored public health system.

The highest number of health personnel work at the lowest level, with decreasing numbers at the sub-provincial, provincial, and national levels. Duration and intensity of training for health workers at the local, sub-provincial, provincial, and national levels increases, with the highest levels of training and responsibility focused on the national level.

The public health systems in developing countries are usually divided into three levels: (1) the central administrative level, which develops and recommends health policies for the entire country and administers national programmes, national training institutions, and national hospitals that provide complicated tertiary care; (2) the provincial health departments, which are responsible for implementing national policies and programmes, and provincial hospitals, which often see referrals from the local health-care facilities and for conducting regional training programmes for local health professionals and volunteer health workers; and (3) the local or district level, which implements national and provincial programmes, such as maternal/child health programmes and vaccination campaigns (Fig. 11.8.1).

The district level (health centre or health post) usually provides a minimum package of activities and healthcare to a population of approximately 5000–10,000 each, and a referral hospital for a complementary package of activities. The health force at the village or commune level includes volunteer health workers who are selected from the local population and provide minimal first aid and referral to the district health centre or hospital. They also help organize immunization sessions, give oral vaccinations (e.g. polio) and high-dose vitamin A to children, but are not allowed to give injections. In addition they promote health education activities, including promoting environmental sanitation. The position carries with it a level of prestige that is its main reward. Volunteer health workers usually receive training for several weeks. Nurses and/or nurse midwives, who also operate at the district level, receive training for 1 or more years and are responsible for childhood immunizations, family planning, maternal and child health-care, and delivery of treatment for tuberculosis and HIV which require daily observed treatment.

Responsibilities/roles of public health professionals at each level in developing countries

Levels of training and duration vary, depending on the role that the graduate is expected to play in the health system. At the highest level, usually for bachelor's or master's programmes, the trainee will receive instruction in administration of health programmes (although care is usually taught through the medical education system), content and strategies for health education, and behaviour modification to achieve a healthy lifestyle, the strategies for assuring a safe water supply, appropriate disposal of human and other waste products, oral health, systems of health financing, control strategies for the major infectious diseases affecting the country (which usually include tuberculosis, malaria, parasite infections,

Fig. 11.8.1 The health system.

Reproduced by kind permission of Dr Lo Veasnakiry.

and HIV, plus any locally endemic diseases), and administration and strategies for immunization programmes. Some developing countries require a medical degree or other health science or a technical degree as a prerequisite for entering into a Master of Public Health (MPH) programme. Graduates of these programmes are expected to lead public health programmes. Programmes at this level usually require the trainee to complete an internship in the field at the local or rural level to ensure their understanding of the system and the culture of the populace at the point of delivery. Research methodologies, if available, are usually taught in the relatively few PhD/doctoral programmes in medical and public health institutions. However, many developing countries are only recently investing in schools of public health and in most research is not conducted. Recently there has been a movement to use the Internet to provide distance learning for public health at the MPH level and for postgraduate/refresher courses that target developing countries, which are offered through various universities and government agencies (Mokwena et al. 2007). Although these programmes are probably quite useful for teaching methodology and public health strategies, they may have difficulties in training relevant to practice at the local level in different countries, as they cannot offer hands-on field experience. One strategy to overcome this difficulty is to have discussion sessions on specific topics through the web, which include practitioners at the local level. Because most developing countries do not have the resources to invest in research programmes most public health programmes are not evidence based.

At the village level, many countries employ volunteer health workers who have had only a few weeks of training and perform very routine functions, such as tending to minor wounds, routine first aid, and encouraging villagers to take their medications as recommended by physicians and allied health workers at the district or higher levels. They usually have the best knowledge of the village and the villagers in terms of health status and needs, and assist more highly trained health professionals. They may receive some remuneration from the villages, but are not usually paid by the ministries of health.

A typical health structure at the district/township level is presented in Fig. 11.8.2.

Health professionals at the lower levels also include nurse midwives and allied health personnel who usually have 1–3 years of training. Nurse midwives are responsible for pregnant women in the district, encouraging enrolment in prenatal programmes, staffing the antenatal clinics, delivering babies, and providing postnatal guidance. They need to be able to recognize difficult pregnancies that will require more highly trained medical personnel to ensure safe delivery. These problem pregnancies are usually referred to the station or higher-level hospital. Transportation to the hospital, particularly in emergency and complicated deliveries, can be a problem. Allied health personnel in districts with nurse midwives usually perform the other medical, sanitation, and health education roles, and direct and facilitate health campaigns such as the polio immunizations days. In some countries, nurse midwives perform both roles, although they may be assisted by assistant nurse midwives who have had less but some training. Nurse midwives may be responsible for as many as 10–15 villages. The rural and urban health centres may have facilities for care of patients, including injuries requiring more than simple first aid. Patients with complicated illnesses, however, are referred to station or provincial-level hospitals, and are diagnosed and treated by physicians. The station hospitals may have a laboratory to perform routine procedures, but are usually not able to do more sophisticated biochemical and microbiological assays, which are usually done at the provincial level.

One problem with the laboratories at each of the different levels is that quality control procedures are often not implemented and standardized. Few of these laboratories participate in quality control programmes, although some wealthier developing countries (e.g. China) have implemented quality control programmes at the county and provincial levels. Thus, there is a problem with quality control and safety in many of these laboratories (Callaway 2012). A second problem is staffing these laboratories with well-trained, competent technicians who are periodically required to update their laboratory skills to ensure valid results and safe procedures.

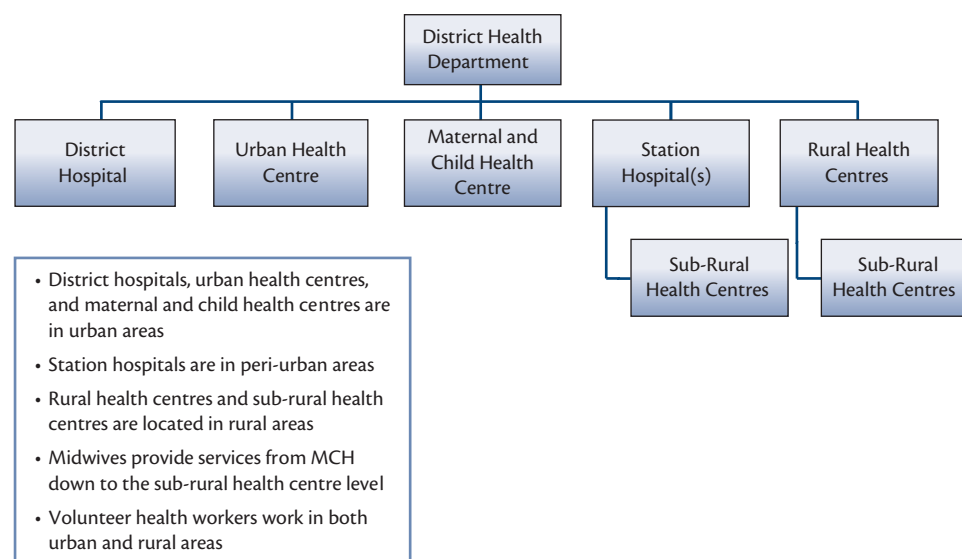

Fig. 11.8.2 Health structure/system at the district level.

Complicated surgical procedures and medical management of serious health problems are usually performed only at the provincial and national/tertiary levels. A serious problem in developing countries with limited resources and populations in remote areas is diagnosis and transport of patients to tertiary care facilities with sufficient speed to ensure successful treatment.

Training of health workers may occur at each of the levels of the public health system, although training of higher levels of health professionals is usually limited to universities, medical schools, and schools of public health, dentistry, health sciences, and nursing.

Education for health professionals in developing countries

In all developing countries, completion of medical school is required for healthcare professionals working in the various healthcare facilities at the national and provincial levels and district-level hospitals. Many developing countries require graduating physicians to work a minimum number of years at the district level as a strategy for providing healthcare at the peripheral levels of the health system. A medical degree is often also required at the national and provincial levels for staff responsible for administering national programmes. Specialized medical training is usually only required at the national-level healthcare facilities, and sometimes at provincial-level health facilities. Specialized training is usually required for health professionals conducting dental care and pharmaceutical services.

Advanced training is required for health professionals who will design and direct health information systems such as disease surveillance, and who will design and conduct health research to inform policy decisions and evaluate health programmes. These activities are usually directed at the national level, although they may involve staff at the provincial, district, and local levels.

Nurses usually require bachelor's degree-level training. However, midwives who work at the district level may receive an associate midwife degree, which may require only 1–3 years of certificate-level training, depending on the country. Some countries also have midwife assistants who receive shorter training. Staff providing lower-level nursing, medical imaging, sanitary services, low-level laboratory services, and physical therapy usually have limited training.

Problems with providing public health training in developing countries

Health professionals at the district level, who often have had only 1–3 years of training, are expected to assist in planning and management of public health programmes, recognition of the need for and initial conduct of outbreak investigations, implementation and monitoring of immunization programmes, prevention, treatment, and monitoring of tuberculosis and HIV programmes (e.g. directly observed therapy), programmes to prevent malaria (e.g. bednet distribution and mosquito control programmes), and basic health education in strategies to prevent disease and promote healthy lifestyles. Their training may not include training in the various skills and knowledge required to carry out these responsibilities, including the need for collection of accurate data that can be used to plan and support effective health systems (International

Institute for Viral Registration and Statistics 1989). Thus, there is a need for congruency in the training of public health professionals and the responsibilities they will assume (Sudhinaraset et al. 2013). A major barrier to achieving proper training at all levels of public health training is the scarcity of qualified faculties in these programmes. Refresher training for health workers is important to ensure that they keep up with current and changing strategies and policies. The training of health professionals at the local level is often not integrated, so that staff members know only their own responsibilities but do not have a holistic understanding of where their efforts fit into the broad public health system.

Funding for public health programmes and training is often a low priority for political leaders and decision-makers. The majority of health programmes in developing countries are subsidized by international donors who have their own health agendas, and which may differ from those of the country.

Clear public health career tracks are often not apparent for qualified individuals who wish to choose a career in public health. Further, public health professionals at every level are usually not paid well. Often physicians who are willing to work in public health must also have private practices to generate enough income to support their families (Chomitz et al. 1998; Ferrinho et al. 2004). Thus, they are not able to dedicate their full efforts to their public health responsibilities. Physicians are often reluctant to work in remote rural areas (WHO 2010a). Public health workers at the peripheral level are usually paid low wages or are expected to volunteer their services. In these situations, other reward structures must be created to motivate volunteers and low-level workers (Henderson and Tulloch 2008; Mangham and Hanson 2008).

Strategies to overcome barriers to optimal public health training

The fundamental principles for designing public health training involve both academic and practical components. For training programmes to be responsive to needs, the needs must be clearly delineated. It is important that the tasks and responsibilities of health professionals at every level of the public health system be designed to meet the needs of the constituency and the level of responsibility expected at that level. A first step is to conduct needs assessments at each level, from the local and provincial levels to the national level, and from the village health worker to the researcher and the policymaker (Bangdiwala et al. 2010). The assessment should involve members of the community or constituency at that level. Formulation of the responsibilities and tasks at each level can then be clearly defined, and documentation of formal job descriptions provided so that an appropriate training curriculum may be developed for health workers expected to perform the required tasks at that level of the system. Training resources should then be identified and/or developed for the required training at each level of the public health system. At each level, the curriculum should be designed and evaluated for responsiveness to the job descriptions of the positions that graduates are intended to fill. The faculty of the training programmes at each level should include individuals who have had experience in delivering services at that level. The training should include providing an understanding of where the responsibilities of the health professional being trained fit into the public health system of the country.

It is important for those designing public health systems to delineate clear career paths for health professionals at each level. Defining these career paths will inform and, if done well, attract potential students to pursue those careers. An important component of defining career paths is to include incentives for individuals in these career paths (Calcutta Declaration, 1999). A problem in many developing countries is the high attrition rate of trained health volunteers, in part due to a lack of monetary incentive. In some developing countries, training, especially for nurses, may better prepare trainees for work in developed countries. Thus, migration of health professionals, particularly doctors and nurses, to better working conditions and pay in developed countries reduces the potential workforce, whose training was funded by the developing countries (Stilwell et al. 2004; Naicker et al. 2009; WHO 2010b). In these situations, developing countries may be considered to be subsidizing healthcare in developed countries!

Incentives for health workers should include monetary rewards, but it is important that they also include recognition of the importance of the health professionals at every level in the entire system in advancing the health of their constituencies. This recognition is particularly important at the lowest and least financially rewarding levels. Prestige and recognition of worth are powerful incentives!

Assuring that the public health system remains responsive to changing needs

Finally, it is important to monitor and periodically evaluate the performance of the health system at each level. Over time, specific needs change, due to a range of factors; therefore, training programmes may no longer prepare trainees for the changing needs of the constituency at that level, and must adapt their training to current needs. In addition, previously trained workers need to update their skills. Thus, it is important to also include postgraduate training at all levels for health workers that will recognize and retrain health professionals to meet the changing demands on the health system.

Summary

A well-designed, responsive public health system is essential for the well-being of citizens of developing (as well as developed) countries, and must be a government priority. The effectiveness of the health system ultimately depends on the quality, ability, and performance of the people who work in the system. Appropriate and competent training for health workers at each level is therefore essential to the effectiveness of the health system and, ultimately, the health of a country's citizens, and must include postgraduate/

refresher training to ensure the continued competency of the public health workforce.

Training of local health workers to meet public health needs

Piya Hanvoravongchai and
Suwit Wibulpolprasert

Introduction to training of local health workers to meet public health needs

People are living longer. Globally, life expectancy at birth has increased substantially over the past 40 years (Wang et al. 2012) with fewer premature deaths and a shift of disease burden from communicable, maternal, neonatal, and nutritional causes to non-communicable diseases (NCDs) (Murray et al. 2012). However, longer life does not necessarily mean better health or less healthcare needs. While world populations are ageing, there are also more people living with diseases and disabilities. Promoting health and preventing disease burden is a priority, especially in the fight against NCDs and the unfinished agenda of the Millennium Development Goals. The global commitment to reduce relative mortality from NCDs by 25 per cent by 2025 (World Health Organization (WHO) 2012a) requires additional financing, health workforce, and social and legislative measures, through various strategies, such as enforcing tobacco control, reducing population salt consumption, improving diets and increasing physical activity, reducing harmful consumption of alcohol, ensuring access to essential drugs and technologies, and providing appropriate medical care to those with high risk of cardiovascular diseases (Beaglehole et al. 2011; Bonita et al. 2013). The increasing threats of emerging diseases and re-emerging infectious diseases and the possible negative health consequences from climate changes also require health systems preparedness and active responses from the healthcare sector and its health workforce.

'Health workers', as defined in *the World Health Report 2006*, includes 'all people engaged in actions whose primary intent is to enhance health' (WHO 2006). Health workers are one of the six crucial building blocks of health systems. They are key for improving health service delivery with regards to equity, quality, efficiency, and accessibility. They also manage all other financial and non-financial resources in the health system. Moreover, investing in health workers accounts for a large share of public health spending in most countries. Nevertheless, there are a number of challenges for health workforce systems globally, including shortages and inappropriate distribution of key health professionals,

as well as poor workforce performance and weak management (Chen et al. 2004; Haines and Cassels 2004). The current weakness of health workforce systems in many countries is a major obstacle to providing necessary health services to achieve national health targets and internationally agreed-upon health-related development goals (Chen et al. 2004; Haines and Cassels 2004; Travis et al. 2004; WHO 2006; Kanchanachitra et al. 2011).

One of the strategies being proposed to address these challenges is the 'task shifting' concept, whereby some specific tasks are assigned or delegated to health staff or workers who have less training (Hanvoravongchai 2007; McPake and Mensah 2008). Evidence, especially from low- and middle-income countries, indicates that task shifting is an important policy option and the results can be as effective as when professionals carry out those tasks (Huicho et al. 2008; Callaghan et al. 2010; De Brouwere et al. 2009; Fulton et al. 2011). Using human capital effectively through adequately trained but not over-qualified staff is considered one of the key principles driving healthcare delivery innovations for the next century, together with more active involvement of patients and communities in health service delivery (Dzau et al. 2012). Non-professional health workers, such as community and local health workers, are being recognized as valuable assets for implementing effective health system interventions (Singh and Sachs 2013; Tulenko et al. 2013).

Who are the local and community health workers?

Local and community health workers (L/CHWs) are terms that have been used interchangeably to refer to non-professional health staff who work in local communities. The WHO defined community health workers as 'people with limited education who are trained in a short time to carry out either a wide range or restricted aspects of healthcare services' (WHO 1978, 1987). They include: 'men and women chosen by the community, and trained to deal with the health problems of individuals and the community, and to work in close relationship with the health services'.

L/CHWs may vary in terms of labels in different countries and in different situations, their basic education and training periods, and their responsibilities. For example, they may be called community health workers, village health volunteers (VHVs), village health communicators (VHCs), health guides (HGs), sanitation monitors, barefoot doctors, feldschers, health guides, lady health workers, community health advisors, or health extension workers. In many countries, there are multiple categories of L/CHWs in a community.

Countries use L/CHWs to fulfil many public health-related roles, and they constitute a major workforce for public health in many developing countries. The statistics on the numbers of local and community health workers are limited. The *World Health Statistics 2012* (WHO 2012b) reported that between 2005 to 2010, for the countries where data was available, there were over 1 million L/CHWs in China, approximately 50,000 each in both Bangladesh and India, 25,000 in Ethiopia, almost 20,000 in Nigeria, 10,000 each in both Malawi and Pakistan, and smaller numbers in several other African countries. In Thailand, it is estimated that there are approximately 1 million village health volunteers serving the country's population of 65 million. Although they prominently serve in low-income developing countries, L/CHWs also serve in higher-income countries. For example, in the United States, the American Public Health Association (2009) defines community health workers as 'the frontline public health workers who are trusted members of and/or have an unusually close understanding of the community served'. They may be called *Promotores de Salud*, community health representatives, community health advisors, etc. The US Centers for Disease Control and Prevention maintains a database of local and community health workers that contains information on over 10,000 workers in more than 200 programmes (Rosenthal 2000).

L/CHWs are usually recruited from the community, with involvement of the local community in identifying suitable candidates (Bhutta et al. 2010). Some are tested for their literacy and numeracy, and interviewed by judges to explore their motivation and willingness. Given the necessary role as a link between the local community and local healthcare providers, both sides usually have influence in the final selection. The World Health Organization (1989) proposed that L/CHWs should be:

- ◆ Members of the communities in which they work.
- ◆ Selected by the communities.
- ◆ Answerable to the communities for their activities.
- ◆ Supported by the health system but not necessarily a part of its organization.
- ◆ Less trained than professional workers.

Frontline workers, such as community health workers and village health volunteers, have improved healthcare coverage and increased health equity. The linkage to both the community and local healthcare providers enables local and community health workers to serve as intermediaries who promote trust and facilitate access to healthcare services and delivery of public health interventions (Bhattacharyya et al. 2001). They play essential roles in bridging the gap between the community people and healthcare professionals. They also help with community mobilization and capacity-building processes.

After several decades of development, ample evidence has been published regarding the L/CHW role as a key agent in improving health. In Africa, the use of community health workers has been found to improve health development (World Bank 1994; Gericke et al. 2003; Lehmann et al. 2004; Perry et al. 2014). In certain communities, they can satisfy basic healthcare needs that cannot realistically be met by other means (WHO 1989). L/CHWs are generally better distributed geographically (Berman et al. 1987; Chapman et al. 2005) and there is little or no 'external brain drain' of this workforce. They are also more accessible and acceptable to communities, resulting in an increase in health service utilization, especially among poorer households (Berman 1984; Berman et al. 1987). Extending services through L/CHWs is seen as a way to reduce inequity in child healthcare (Victora et al. 2003; Masanja et al. 2005; Haines et al. 2007). A systematic review of the interventions carried out by community health workers found that health interventions such as tuberculosis treatment, immunization, promoting breastfeeding, and interventions reducing other agents of child morbidity and mortality are as effective when delivered by L/CHWs as by professionals (Lewin et al. 2010).

Roles and responsibilities of L/CHWs

To respond to public health needs, L/CHWs have many roles and responsibilities (Box 11.9.1). They are usually regarded as health leaders and health advisors in the community in which they work. They work as educators, communicators, detectors of problems, and problem-solvers. They provide information that promotes individual and family self-care and responsibility as integral components of everyday life. They sometimes play an important role in stimulating communities for action as community organizers.

Other than roles as educators and motivators, most L/CHWs, especially those in developing countries, are also engaged in delivering first-aid treatment and dispensing basic medications (WHO 1987). Some L/CHWs support delivery of general basic health services; for example, village health volunteers in Bangladesh, Bhutan, and Thailand. L/CHWs in Botswana, Sudan, and Yemen provide regular school health activities, and L/CHWs in Botswana, Jamaica, China, and Papua New Guinea assist in health centre clinic activities. More specific or sophisticated service is conducted only by L/CHWs in some countries. For example, in Columbia and Papua New Guinea, L/CHWs also give injections, particularly for immunization (WHO 1987).

In some countries, local or community health workers are assigned specifically defined tasks that require special trained skills. For example, in Pakistan, lady health workers are women recruited from the same community for which they serve, to provide reproductive health services and to promote positive health behaviours. In Bangladesh, the Shasthyo Sebika is trained to deliver directly observed treatment for tuberculosis and sell essential medications. The increasing interest in 'task shifting' to enable rapid scale-up of key health interventions and increase productivity of health professionals means more skilled tasks may be allocated to paraprofessionals and local health workers (Lehmann et al. 2009). For example, local health workers may be assigned to deliver specific health or medical interventions, such as vaccinations, malaria control, assisting pharmacists, or implementing HIV/AIDS screening, testing, and adherence monitoring (Bhutta et al. 2010; Callaghan et al. 2010).

Box 11.9.1 Various roles and responsibilities of local and community health workers reported in earlier studies

- ◆ Provide first aid to accident victims and treat simple illnesses.
- ◆ Dispense basic essential drugs.
- ◆ Give pre- and post-natal advice and motivation.
- ◆ Deliver babies.
- ◆ Provide childcare advice and motivation.
- ◆ Perform school health activities.
- ◆ Stimulate nutrition motivation and give demonstrations.
- ◆ Implement nutrition actions (weigh children, maintain charts, and distribute food supplements).
- ◆ Promote immunization and give injections.
- ◆ Promote family planning and distribute supplies.
- ◆ Promote environmental sanitation, personal hygiene, and general health habit motivation.
- ◆ Implement communicable disease actions including surveillance, screening, referral, prevention, motivation, and follow-up.
- ◆ Conduct non-communicable disease screening, referral, prevention, motivation, and follow-up.
- ◆ Assist health centre's clinical activities (i.e. not in village).
- ◆ Refer difficult cases to health centre or hospital.
- ◆ Collect vital statistics, maintain records, report community health status and problems.
- ◆ Visit homes of disabled, elderly, and community members with health needs on a regular basis.
- ◆ Inform, educate, and empower community members about public health issues.
- ◆ Provide informal counselling and social support.
- ◆ Advocate individual and community needs.
- ◆ Mobilize support and partnership between the community and local health facility.
- ◆ Perform tasks outside the health sector (e.g. agriculture).
- ◆ Participate in community meetings and community campaigns.

As a trusted member (and leader) of the community, L/CHWs can integrate health issues into other community development activities, a role that could be difficult for health professionals. In many countries, L/CHWs combine service and developmental functions that are not confined to the field of health. The relative importance of these two functions varies according to socioeconomic situations and the availability and accessibility of local health services. The service function is less important where there is ready access to healthcare facilities. The developmental function is useful in all circumstances, and is crucial in less developed communities. Walt (1990) concluded that L/CHWs not only provide basic health services, but also promote the key principles of primary healthcare; that is, equity, intersectoral collaboration, community involvement, and use of appropriate technology.

Competency-based training

Because L/CHWs are recruited from the community where they reside, there can be enormous variations in their background knowledge and skills. Training is necessary, and must be designed to be appropriate for the local community health problems, the existing capacity, and the roles and responsibilities they are expected to assume. The prerequisite of any training programme is a full understanding of the expected competency of L/CHWs.

Training programmes should be designed to address the local needs, and designs of the programmes may vary according to the health system context and the roles of L/CHWs. 'Competency-based' training or education is an approach frequently advocated to ensure that the teaching and learning processes lead to the expected outcomes.

‘Competence’ or ‘competency’ is defined by the WHO as ‘the acquisition of sufficient knowledge, psychomotor, communication and decision-making skills and attitudes to enable performance of actions and specific tasks to a defined level of proficiency’ (WHO 2011). Competency-based training therefore focuses on ensuring that all trainees will acquire necessary knowledge, skills, and attitudes to fulfil their roles. This differs from the previous paradigm of top-down teaching and being trainer-oriented.

In practice, the training programmes for L/CHWs vary greatly across countries and regions. Most L/CHWs are volunteers and receive short but systematic training. Some L/CHWs receive longer-term training and may have appointments as government officers, for example, auxiliary midwives in Myanmar and community health aides in Jamaica. The major determinants of the training programme tend to be the underlying characteristics of the individuals recruited for training, the roles and responsibilities they will have, and the nature of health problems they will encounter. Designing a competency-based training programme for L/CHWs therefore requires an understanding of the existing health problems in the community, the roles and responsibilities that they will take in relation to other health professionals and staff, and the tools and support that will be available to them.

Competency-based training requires the learning process to be problem and practice based so that relevant skills and attitudes can be developed and fostered. An excellent L/CHW training programme should lead to ‘transformative learning’, whereby trainees acquire knowledge, skills, and attitudes that change their perspectives and mindset and enable them to be active leaders or ‘change agents’ for better health and well-being of the populations in their communities (Frenk et al. 2010). Training assessment at the end of the training programme should also be designed to evaluate the competency sets that the trainees are expected to have. Following up their activities in the community can also yield additional input to further revise the training programme or to determine whether additional ‘on the job’ training is required.

Desired competency sets of L/CHWs

Competency sets that are expected to be learning outcomes of the training programme should include both *general competency* and certain *specific competency* sets. The level of competency in each set can also range from simply being aware, being knowledgeable, or being proficient. For example, L/CHWs should have good communication skills, but need only be knowledgeable about disease symptoms and complications and aware of specific treatment options for diseases prevalent in the community. Moreover, the discipline-specific competency sets can differ based on the expected functions and responsibilities of each workforce. For example, some types of local health workers may require broader knowledge of a disease that they will encounter, such as HIV/AIDS or malaria. The overall competency sets need to be designed based on the context and the roles these local health workers will have.

General or cross-cutting competencies should include general skills in communication, advocacy, and teaching. Health workers should have the attitudes of public altruistic mindset, empathy, equity, etc. They should be culturally sensitive and have good interpersonal skills. Moreover, each L/CHW should have general work skills such as literacy and numeracy, computer literacy, and presentation, writing, and basic analytical skills. Leadership, time management, and

financial management skills would also be necessary for L/CHWs who are expected to become local leaders for positive changes. Burns (2002) proposed the following seven areas of generic competency for any workers, which are also relevant for L/CHWs:

1. Knowing how to learn.
2. Reading, writing, and computation skills.
3. Communication skills: effective speaking and listening.
4. Adaptability, problem-solving skills, and creative thinking.
5. Personal management for personal and professional growth.
6. Group-related competency: interpersonal skills, teamwork, and negotiation.
7. Leadership and organizational effectiveness skills.

Specific competencies may include knowledge about health and diseases, including dental and mental health. Community health workers should have knowledge and basic skills related to common infections and health risks, as well as basic epidemiology. Non-health disciplines such as law may also be useful. In addition to discipline-specific competency, the desired competency may be subject-specific such as maternal and child health, HIV and sexually transmitted diseases, vaccine-preventable diseases, disease surveillance, NCDs, health promotion, education for behavioural change, and long-term care. For specific tasks, function-specific competency would be necessary, such as community leadership and capacity-building, population and community assessment and problem-solving, clinical care coordination, home visits and outreach strategies, and health insurance enrolment. L/CHWs who are expected to work with specific populations in their community, such as vulnerable populations or populations at risk, underserved populations, and hard-to-reach populations, may need additional skill sets and cultural sensitivity. The combination of general and specific competency areas to be included in the desired competency sets needs to be designed and agreed upon by the organizers of training programmes. Expected competencies can vary within and across countries and regions.

In South East Asia, the WHO proposed a framework for the core competencies of local health volunteers based on the community and home-based health development model to be adopted and adapted by the countries (WHO 2004). Their proposed core competencies cover three key areas: basic medical care, health promotion, and disease prevention. For basic medical care, the volunteers are required to have skills for interviewing, observing, assessing mental health, and other basic skills for laboratory test interpretation and decision-making for referrals and emergency management. For health promotion, the trainees should acquire necessary knowledge and skills for counselling and to assess growth and development of children. For successful disease prevention, certain skills are required, such as giving injections, detecting emerging diseases, and additional knowledge and skills for community health assessment and problem detection, such as family violence, drug use, and community mental health.

Designing an effective L/CHWs training programme

As mentioned earlier, an effective training programme needs to be designed carefully to address local health problems, inform

about the local health system context, and train for expected competencies. Designing a good training programme therefore requires good preparation, starting with appropriate local workers or candidates being recruited, through later steps of training programme evaluation and post-training support. These can be summarized into six key steps as following:

1. Recruitment and needs assessment.
2. Curriculum preparation.
3. Selecting training period and timing.
4. Selecting learning methods.
5. Monitoring progress and evaluating training results.
6. Post-training support.

Recruitment and needs assessment

Recruitment of L/CHWs is an important step in the training programme design. Selection of the workers is generally based on their linkage to the community with community involvement in identifying potential L/CHWs. However, additional entry criteria are also required. Willingness to work for the community and to gain new knowledge and skills is a very important precondition for an effective local health workforce. This can be assessed through an interview by community leaders and representatives from local health centres. In addition, for countries with low achievement in basic education, it is important to screen for literacy and numeracy, which are necessary for the training processes. Such skills cannot be expected to be developed by the L/CHW training programme.

After recruitment, trainees should be assessed for their basic knowledge and skills. Their level of existing competencies will give an understanding of the training needs, based on current gaps. The scope and content of training programmes can then be appropriately designed.

Curriculum preparation

The training curriculum can be likened to a map to guide a traveller to the correct destination. The local health worker training curriculum should be prepared to accommodate the training needs and the practicality of its implementation. The training curriculum should include the scope and the content of the training, how it is organized, the learning activities, information on the roles of the trainers and the trainees, the training materials that will be used, and the type of evaluation that will be implemented to assess the progress and achievement of the trainees. Many training programmes develop customized curricula to match specific groups of trainees. They use common core resources and incorporate additional lessons and best practices from the community or region they are working with. An example of the key components of rural health workers' training curricula proposed by the US Rural Assistance Center is provided in Box 11.9.2 (Rural Assistance Center 2012).

The training curricula may cover broad skills and competency training for general local health workforces or specific programmes/skills training for specialized health workers. The design of the curriculum must recognize that its implementation may require flexibility especially when carried out in the field. A national curriculum should provide room for local adaptation, as it may need to be adjusted to take into account the diversity in

Box 11.9.2 The curriculum for a rural health workers training programme

The US Rural Assistance Center, in its community health workers toolkit, proposes that the rural health workers' training curriculum should include, but is not limited to, the following components:

- ◆ Training on accessing healthcare and social services systems.
- ◆ Translating, interpreting, and facilitating client–provider communications.
- ◆ Gathering information for medical providers.
- ◆ Delivering services as part of a medical home team.
- ◆ Educating social services providers on community/population needs.
- ◆ Teaching concepts of disease prevention and health promotion to lay populations.
- ◆ Managing chronic conditions.
- ◆ Home visiting.
- ◆ Understanding community prejudices.
- ◆ Patient privacy.
- ◆ Safety.

the context, the situation, and the participants. In certain situations, participatory curriculum design is needed when the course contents and methods are shaped by the interactions between the trainers and trainees.

Training period and timing

As part of the curriculum, the training period and timing should be specified. An effective L/CHWs training programme should cover both pre-service and in-service training. *Pre-service* training refers to the training that the L/CHWs receive after their recruitment to prepare them for their service. It usually includes teaching of basic theories and preparation of knowledge and skills for their practice. *In-service* training is the training provided to active L/CHWs who are already working in the community. It is as important as initial training, and can be either *refresher training* to remind the workers of the previous curriculum or training of *new knowledge or skills* to carry out additional services, or both.

The period of training may vary according to the level of training requirements, which reflects different roles and training needs across countries and programmes. Table 11.9.1 shows the training periods of various L/CHW programmes in sub-Saharan African countries (Funes et al. 2012). The formal or informal role the trainees will play in the system influences the length of the initial training. Training of volunteer or informal health workers is generally shorter than a week, while training of other community health workers with formal roles could take longer. Training of health extension workers in Ethiopia and Nigeria lasts longer than

Table 11.9.1 A summary of pre-service training programmes in some sub-Saharan African countries

Length of training	Illustrative names	Roles in health system	Minimum education	Example countries
< 1 week	Village health worker/volunteer	Informal	None	Senegal, Nigeria, Ghana, Tanzania, Mali
1–2 weeks	Village health worker	Formal	Primary school	Uganda, Rwanda
2 months–1 year	Community health workers	Formal	High school	Zambia, Ghana, Kenya, Malawi, Mozambique
> 1 year	Health extension workers	Formal	High school	Nigeria, Ethiopia

1 year (Funes et al. 2012). The period of refresher training and new skills training is generally short.

In Thailand, the Village Health Volunteer (VHV) Training Curriculum is compulsory for all new recruits or those serving more than 5 years. The training experience covers two courses, main and elective. At the end of the training programme, the participants are expected to have taken the following eight subjects: primary healthcare, village health volunteer, laws related to VHVs, staying healthy and having a happy life, necessary public health services, communication in primary healthcare, planning of community projects, and management. Trainees can also take additional 6-hour elective courses, such as communicable or NCDs.

Bhutta et al. (2010) compiled a review of community health worker programmes for the Global Health Workforce Alliance. They proposed a recommended framework for training that includes 6 months of pre-service or initial training, another 6 months for on-the-job training, and monthly training for new knowledge and skills. Refresher training can be taken every 6 months.

Timing of training is also a very important factor for both pre-service and in-service training plans. The design of the training programme should carefully explore the most suitable timing for training that may vary across communities. L/CHWs, especially health volunteers, usually have other daily activities that may require most of their time. They may also be involved in other community actions that make demands on their free time. In some agrarian-based societies, villagers may not be able to attend any training activities during the busy seasons of farming or harvesting crops.

It is also important to coordinate the training schedule and harmonize the training curriculum across programmes or projects to avoid duplication and improve efficiency. One study in sub-Saharan Africa found that, in addition to the ministries of health and government agencies, there were more than 20 organizations that train community health workers in the region. In many countries, there were more than ten organizations providing health worker training, and some were in the same location but without coordination, leading to duplication (Funes et al. 2012).

Selecting learning methods and learning experience

L/CHWs are adults who are recruited from the community. Their levels of knowledge, skills, and life experiences may greatly vary. Understanding adult learning theories and practices can be useful

for effective design of the training programme experience. The learning processes must be an important consideration when designing teaching for adults. According to Malcolm Knowles, who is sometimes referred to as the father of adult education, adult learning is different in many ways from child learning. He proposes five common characteristics of adult learners as shown in Box 11.9.3 (Merriam 2001). As summarized by James Clawson (2006), 'Adults don't learn like children. Adults are more discerning in what they are willing to learn, more questioning, and more resentful of being told what to learn'.

Therefore, teaching adults should not be didactic, but emphasize learning approaches that are problem-based and collaborative. The interactions between teacher and learner should also be based on a more equal relationship. Based on the adult learning theory, adult training should be 'student-centred, experience-based, problem-oriented and collaborative' (Burns 2002).

Training methods for L/CHWs in the past emphasized lecture-based learning and focused on the theories and knowledge that may be complicated and not interesting for adult students (Gilson et al. 1989). Classroom-style teaching is also not conducive for skills development, especially for general public

Box 11.9.3 Five principles of adult learning according to Malcolm Knowles

1. Adults have an independent self-concept and can be self-directed in their learning.
2. Adults bring life experiences and knowledge to learning.
3. Adults are goal oriented with their learning needs closely related to their roles.
4. Adults are problem oriented and interested in practical applications of knowledge.
5. Adult learners are internally motivated to learn and want to be respected.

Source: data from Merriam, S.B., *Andragogy and Self-Directed Learning: Pillars of Adult Learning Theory*, in Merriam, S.B., (ed.), *The New Update on Adult Learning Theory: New Directions for Adult and Continuing Education*, Number 89, Spring 2001, Jossey-Bass Higher and Adult Education Series, Copyright © 2001 John Wiley & Sons Ltd.

health competency. Several other learning approaches may be more favourable to adult learning, such as action learning, experiential learning or learning by doing, project-based learning, and self-directed learning (Conlan et al. 2010).

Post-training support

Supervision and support are commonly acknowledged as key functions to the success of L/CHWs. Because they work mainly in the field or in the community, 'regular supervision and support will help maintain the interest and motivation of these workers to carry out their assigned tasks' (Curtale et al. 1995). Despite its importance, supervision and support are often among 'the weakest links in L/CHW programs' (Lehmann and Sanders 2007). Inadequate supervision was found to be one of the main factors limiting the effectiveness of L/CHW programmes (Bhutta et al. 2010). An effective training programme should not end at the conclusion of the training period, but prepare and plan for supervision and support for the trainees over the long term to promote success and sustainability of the programme (Baker et al. 2007).

Distance training and the use of new technologies to provide L/CHW training and support are increasingly mentioned as the trend forwards. With the increased availability of mobile phones and the Internet, effective use of information technology can be employed for training purposes. Digital training materials are also cheaper to transfer and easier to customize and localize. The Dalberg Global Development Advisors (Funes et al. 2012) proposed several reasons to support their prediction that distance learning will play an important role in the future (Box 11.9.4).

Motivation and incentives

L/CHWs are like other health workers who require appropriate motivation and incentives to foster their efficiency and effectiveness. Motivations are mainly internal drive that encourages L/CHWs to

carry out their tasks with happiness. Incentives are usually an external force that drives them to work more effectively. Motivation can be generated through role models, inside understanding of the importance of their works, and realization of the successes and achievements. Incentives may be physical, like financial incentives and some fringe benefits including health benefits, and non-financial ones like the social recognition, opportunity for continuing education, permanent job opportunity, and career development.

Those that are volunteers should focus on using motivation and non-financial incentives. L/CHWs who receive longer training and carrying out formal or more permanent jobs, such as the health extension workers, require adequate financial incentives. Thus each L/CHW programme should properly design an appropriate package for motivation and incentives to ensure long-term sustainable successes. The training programme can also serve as an initial venue to drive the motivation of L/CHWs and to promote an understanding of incentives available for them.

Conclusion

L/CHWs are an important component of health workforce systems. They can be trained to carry out basic tasks and specific functions to support health professionals and other types of health workers in delivering health services. They also have closer links to the community and generate more trust.

To ensure that local health workers have adequate competency to fulfil their roles, effective training programmes are needed. Training can be both pre-service and in-service and include new knowledge and skills or refresher training. Training can be about core public health knowledge and disciplines, as well as general work competency, such as communication and leadership skills. The training curriculum should be well designed to accommodate the needs and the practicality of its implementation and take into account the adult learning theory in the choices of training methods and learning experience.

Designing an effective training programme should start from the recruitment process and must ensure that the system of support and recognition is in place after training is completed. This requires strong political support for the local health worker programme, intersectoral approaches to training and functions of these workers, and active community participation in recruitment and support. In addition, an effective incentive package should be incorporated in the L/CHW programme to build up motivation of the L/CHWs as well as to provide appropriate financial and non-financial incentives to ensure long-term sustainable success of the L/CHW programme.

Box 11.9.4 Five reasons why distance learning could play an important role in L/CHW training

1. Implementers can more easily reach L/CHWs who live in remote, difficult-to-access areas.
2. By permitting L/CHWs to learn within their communities, distance learning can support continuity of care.
3. Distance learning would obviate the burdens of travel for L/CHWs and reduce time spent away from household management or employment.
4. L/CHWs could learn at a flexible pace, refresh their knowledge in short modules, and learn continuously.
5. By relying on communication technology, supervisor support and peer networks can be facilitated.

Emergency public health and humanitarian assistance in the twenty-first century

Les Roberts and Richard Brennan

Introduction to emergency public health and humanitarian assistance

Examples of humanitarian actions likely precede recorded history. Zakah, a pillar of Islam, the New Testament story of the Good Samaritan, the central theme of mercy in Buddhism, and similar concepts in almost all religions suggest that the systemization of compassion towards those in crisis may be an inevitable manifestation of social organization. Thus, it may be surprising that the science, and in particular the health science, associated with responding to natural and man-made crises has mostly developed in the past half century.

During the Biafran War (1967–1970) perhaps half of the 2,000,000 population inside the shrinking breakaway enclave died of malnutrition and disease by the end of the conflict (Western 1972). During this crisis, profound advances in modern humanitarian relief arose. Unable to determine which children were starving and which children were just skinny or small, the Friends Overseas Service Committee triggered the development of the Quaker Upper Arm Circumference (QUAC) Stick, the first scheme for assessing nutritional anthropometry. The Centers for Disease Control and Prevention (CDC) tested the universally accepted theory that malnourished children could not produce an immunological response to being vaccinated by using intervention and control groups. They vaccinated some very malnourished children and followed up weeks later by drawing blood from the study children to see if immunity had developed. In this first known controlled trial in an emergency, it turned out that malnourished children could indeed be effectively vaccinated (Ifekwunigwe et al. 1980). Other developments included the first known public health adaptation of capture–recapture methodologies from wildlife biology in order to estimate the number of deaths (and thus the first real-time conflict mortality measurement), the first guidelines for such things as running feeding centres, and the creation of the medical relief organization Médecins Sans Frontières (MSF).

In the crises that followed, more and more central insights into the science of keeping vulnerable people alive and healthy accumulated at an ever increasing rate. The East Pakistan Crisis, by chance arising where an international diarrhoeal research centre was based, brought the advent of oral rehydration therapy

(ORT) (Sack et al. 1970). Relief for Cambodians on the Thai border demonstrated the value of surveillance and rapid assessments (Glass et al. 1980). The famine and conflict in the Horn of Africa in the early 1980s provided the rationale for the caloric content of rations, a two-stage measles vaccination strategy for children less than 9 months, and a variety of other ‘best practices’ (Toole et al. 1988, 1989). By the 1990s, comprehensive outlines of priorities and best practices were in place based on the accumulation of these various lessons learned and documented (Toole 1990; CDC 1992; MSF 1997).

Most of these guidelines were developed based on experiences in settings of extreme poverty and high mortality, where the excess (above the normal) mortality profiles were dominated by infectious diseases, primarily diarrhoea, respiratory infections, and malaria. These cold war era crises often continued for many years with large numbers of people displaced and supported in camps for a variety of geo-political and economic reasons. The world of humanitarian response today has little in common with the Biafran era. Today, most of the world’s displaced have not crossed a border and are displaced within their own country. Many, perhaps most of the world’s most vulnerable displaced are in urban settings. And finally, likely as a result of the developments of the relief community and greater global wealth, few crises in the twenty-first century to date have been associated with extended periods of high mortality, as were seen in Cambodia, Mozambique, Sudan, Somalia, Biafra, the Democratic Republic of Congo (DR Congo), and elsewhere in the last century. Expanding humanitarian efforts have evolved to focus more on issues of suffering, often from chronic or mental health related disorders.

To address these new realities, this chapter will look at four areas where the twenty-first-century humanitarian endeavour is likely to differ dramatically from the twentieth century: preparedness and planning, changing institutional structures and architecture, the evolving public health profile of emergency relief needs, and the role of new and innovative technologies. The role of emergency planning and relief workers has grown, professionalized, and become politicized at a dramatic rate in recent years and we attempt here to create a framework for understanding these transitions.

Definitions and classification

There is currently no universally accepted definition of the term 'disaster'. This lack of standardization can be attributed in part to the broad range of disciplines involved in disaster management. Nonetheless, common to most definitions is the concept of large-scale loss that exceeds a community's own capacity to respond effectively, requiring some form of external assistance.

The United Nations International Strategy for Disaster Reduction (UNISDR) defines a disaster as 'a serious disruption of the functioning of a community or a society involving widespread human, material, economic or environmental losses and impacts, which exceeds the ability of the affected community or society to cope using its own resources' (UNISDR 2010). This definition is also one of several recognized by the World Health Organization (WHO).

Similarly, there is no standard classification system for disasters, although numerous have been proposed. Generally, disasters are associated with the hazards that cause them. They can be classified as either natural or human generated, with subclassifications of each (Table 11.10.1). Natural disasters are often subclassified according to whether they are acute onset or slow/gradual onset, human-generated disasters as intentional or non-intentional.

Epidemiology

According to the Centre for Research on the Epidemiology of Disasters, during the 10 years between 2002 and 2011, on average approximately 700 natural and technological disasters occurred globally each year. These disasters affected around 270 million people annually and resulted in an average of 123,000 deaths (International Federation of Red Cross and Red Crescent Societies

2012). The most severely affected region was Asia, followed by Africa and the Americas. According to a study by the WHO in 2007, most countries had experienced a major disaster over the preceding 5 years.

Those most vulnerable to the public health impacts of disasters are the poor. While 27 per cent of disasters occurred in countries categorized as having low human development, they accounted for 47 per cent of deaths, because of their limited capacities to mitigate, prepare for, and respond to disasters. Moreover, the economic costs run into billions of dollars and a single disaster can set back development many years, with obvious implications for public health programming and health outcomes.

These figures do not include conflict-related disasters, the impacts of which are more difficult to quantify. The World Bank estimated that 1.5 billion people live in countries affected by repeated cycles of political and criminal violence, and fragility (World Bank 2011). Most modern-day conflicts are protracted civil wars, in which civilians are often deliberately targeted and frequently displaced from their communities. Often called 'complex emergencies', they are associated with high rates of morbidity and mortality.

In such conflicts, large numbers of deaths can result from violent injury, as in the Rwandan genocide, the Balkan conflicts of the 1990s, and the recent war in Syria. But in many instances, most deaths are due to the so-called indirect health consequences of conflict—increased rates of infectious diseases, acute malnutrition, and complications of chronic diseases that arise due to societal disruption, population displacement, and breakdown in health services. This has been well described in crises in DR Congo, Ethiopia, Somalia, and Sudan (Toole 1997; Coghlan et al. 2006).

Globally, the most frequent types of disasters are transport accidents, followed by floods, windstorms, industrial accidents, earthquakes, and droughts/food insecurity (Table 11.10.2). Climate change is expected to affect the frequency and severity of floods, windstorms, and droughts, with their associated public health impacts (World Health Organization and World Meteorological Organization 2012). For example, severe droughts and associated food insecurity have occurred at more frequent intervals over the past decade in the Sahel and Horn of Africa. Monsoon-associated floods in Pakistan in 2010 and 2012 were among the most severe ever recorded.

The number of ongoing conflicts is more difficult to quantify, as definitions vary. The Uppsala Conflict Database defines a conflict as a 'contested incompatibility that concerns government or territory or both where the use of armed force between two parties results in at least 25 battle-related deaths in a year. Of these two parties, at least one has to be the government of a state'. Based on this definition there were 37 ongoing conflicts in 2011, of which 27 were intra-state, one inter-state, and nine internationalized (Uppsala Conflict Data Program n.d.).

The highest death tolls from natural and technological disasters have been associated with earthquakes/tsunamis, windstorms, extreme temperatures, and droughts/food insecurity (Table 11.10.2). Total death tolls from conflict have been difficult to estimate and can be politicized. The Uppsala database records only battlefield deaths and omits the indirect deaths referenced earlier. But as has been documented in DR Congo, Sudan, Iraq, and elsewhere, total conflict-related deaths (battlefield and indirect) can be enormous and may exceed those due to all other

Table 11.10.1 Classification of disasters

Natural	Human generated
Acute onset	Technological
◆ Geophysical:	◆ Industrial accident:
◆ Earthquake	◆ Explosion
◆ Tsunami	◆ Fire
◆ Volcanic eruption	◆ Hazardous material release
◆ Avalanche	◆ Structural collapse
◆ Hydrometeorological:	◆ Transportation crash
◆ Flood	Societal
◆ Windstorm	◆ Civil strife
◆ Tornado	◆ Mass gathering
◆ Winter storm	◆ Terrorism
◆ Extreme temperature	War/complex emergencies
◆ Forest fire	
◆ Landslide	
◆ Biological:	
◆ Epidemic, pandemic	
Gradual/chronic onset	
◆ Drought, food insecurity	
◆ Desertification	
◆ Insect/pest infestation (e.g. locusts)	

Table 11.10.2 Frequency, impact, and geographic distribution of major types of disasters, 2002–2011

Disaster	Frequency per year	Average deaths per year	Average number of people affected	Average cost of damage (millions of dollars)	Region with highest frequency	Region with highest deaths
Droughts/food insecurity	24	7732	93,132,500	3328	Africa	Asia
Earthquakes/tsunamis	29	67,974	7,905,700	46,153	Asia	Asia
Extreme temperatures	24	14,598	9,050,800	4222	Europe	Europe
Floods	179	5733	117,584,900	27,804	Asia	Asia
Forest fires	11	70	214,600	2757	Americas	Europe

disasters combined (Burnham et al. 2006; Uppsala Conflict Data Program n.d.).

Moreover, elevations in mortality rates can persist for years after the formal end of conflict, as documented in Angola, DR Congo, and South Sudan. Women and children are almost always the most vulnerable in these contexts. Of the 20 countries with the highest child mortality rates, 15 have experienced conflict over the past two decades. Similarly, of the ten countries with the highest maternal mortality, nine have recently endured conflict. According to the World Bank, no low-income fragile or conflict-affected country has achieved even one of the eight Millennium Development Goals—three of which are health related.

An important aspect of disasters that can expose the affected populations to increased public health risks is forced displacement. According to the *World Development Report 2012*, there were an estimated 72.7 million people forcibly displaced worldwide in 2011—and this number is growing annually. An estimated 14.9 million are refugees, 26.4 million are internally displaced persons (mostly due to violence), 16.4 million are displaced due to natural disasters, and a further 15.2 million displaced due to development projects and activities.

The process of displacement can increase the risk of infectious diseases (e.g. through housing in unsanitary conditions or exposure to disease-carrying vectors), food scarcity and malnutrition, physical violence, sexual abuse, and psychological trauma. Access to health services is often limited and ongoing health programmes (e.g. vaccinations) disrupted. Higher disease rates are often documented among internally displaced persons (IDPs), as the well-developed mechanisms to provide protection and humanitarian assistance to refugees do not always apply directly in IDP settings (Salama et al. 2001).

Different types of disasters are associated with reasonably predictable public health risks and associated patterns of morbidity and mortality (Pan American Health Organization 2000) (Table 11.10.3). Earthquakes are often associated with large numbers of deaths and injuries, but infrequently with major population displacements, food scarcity, or increased risks of communicable diseases. Flash floods are often associated with many deaths, few injuries, damage to water systems, and food shortages. Conflicts are associated with a large number of public health risks and consequences. This type of information can assist with the planning and coordination of clinical and public health services.

In addition to climate change, there are other important global trends that threaten to increase the frequency and impact of disasters. Increasing urbanization, poor urban planning, poor land use, unregulated industrialization, new and emerging infectious diseases, and terrorism, all have the potential to expose greater numbers of people to hazards (United Nations International Strategy for Disaster Reduction 2010; WHO 2011a; Bhui et al. 2012). The Christchurch earthquake of 2011, Bangkok floods of 2011, and Superstorm Sandy in New York City in 2012, all demonstrated that disasters that strike densely populated urban areas have the potential for substantial public health and economic impact. The Nigeria floods of 2012 have brought attention to the issues of settlements in flood-prone zones. The severe acute respiratory syndrome epidemic of 2003 and the H1N1 pandemic of 2009 have demonstrated the need for stronger public health surveillance and response mechanisms. Terrorist attacks across a range of countries have revealed security threats that need to be addressed in disaster planning and mass casualty response plans (WHO 2007).

Table 11.10.3 Short-term effects of major disasters

Effect	Conflict	Earthquakes	High winds (without flooding)	Tsunamis/flash floods	Slow-onset floods	Landslides	Volcanoes	Droughts
Deaths ^a	Many	Many	Few	Many	Few	Many	Many	Varies—many with famine
Severe injuries	Many	Many	Moderate	Few	Few	Few	Few	Rare
Increased risk of communicable diseases	High	Potential risk following all major natural disasters. Probability rising with displacement, overcrowding, and deteriorating sanitation						
Damage to health facilities	Varies. May be specifically targeted and looted	Severe (structure and equipment)	Severe	Severe but localized	Severe (mainly equipment)	Severe but localized	Severe (structure and equipment)	Rare
Damage to water systems	Severe	Severe	Light	Severe	Light	Severe but localized	Severe	Varies
Food shortage	Common	Rare (may occur due to economic and logistic factors)	Common	Common	Rare	Rare		Common
Major population displacements	Common	Rare (may occur in heavily damaged urban areas)	Common (generally limited)					Common

^a Potential lethal impact in absence of preventive measures.

Preparing for disasters—health emergency risk management

The most effective means of reducing the public health risks and impacts of disasters is to employ a comprehensive emergency risk management approach. Emergency risk management (ERM)¹ consists of a continuum of synergistic steps that can reduce the risks and consequences of disasters, including prevention (risk reduction and mitigation), preparedness, response, and recovery. These steps are so closely interconnected that for all practical purposes they should not be considered in isolation from each other. Risk assessments and risk reduction activities directly inform disaster preparedness and response, for example. Moreover, the manner by which agencies respond to an emergency will directly impact the recovery process (WHO 2011b).

ERM for health draws on the disciplines of risk management, disaster management, and health systems. The approach emphasizes managing the risks prior to a disaster occurring so that potential public health consequences may be prevented or minimized. Specifically, ERM entails identifying and reducing hazards and associated vulnerabilities, preparing for and responding effectively to disasters, and recovering, rehabilitating, and reconstructing after a disaster has occurred. Experience has demonstrated that countries and communities that have invested sufficient resources in ERM have responded more effectively and have been more resilient to the effects of disasters. Strengthened ERM also has the potential to contribute to sustainable development.

Bangladesh is one of the most natural-disaster prone countries on the planet. Large numbers of people live on a low, flat alluvial

delta vulnerable to floodwater coming from the Brahmaputra basin to the north and the typhoon-prone Indian Ocean to the south. A typhoon in 1970 resulted in approximately a quarter of a million deaths (Bern et al. 1993). Over the next decades, the people of Bangladesh built 311 elevated typhoon and flood shelters that could hold 350,000 people and implemented community-based response strategies. A similar 1991 typhoon affecting a far larger population resulted in 138,000 deaths (Mallick et al. 2005). During the 1991 storm, seeking a storm shelter early and being in an official shelter were highly protective against death although only 17 per cent of the affected populations sought shelter in response to the storm warning sirens. Since then, advances in storm warning, public communications and community response have resulted in Southern Bangladesh being held up as an example of disaster preparedness (United Nations Development Programme 2010).

Guiding principles

In addition to the emphasis on managing risks, ERM is guided by the following key principles Brennan et al. 2009):

- ♦ *All-hazards.* Many of the key functions required to manage risks are common across all hazards, for example, assessments, communications, logistics, etc. Moreover, it is neither efficient nor cost-effective to develop separate plans, procedures, trainings, rosters, and response mechanisms for each individual hazard. While some hazard-specific considerations will rarely be required (e.g. radio-nuclear), an all-hazards approach allows for more efficient management of risks and responses.

- ♦ *Multisectoral approach.* Many activities required to protect and preserve health are managed primarily by other sectors, for example, water and sanitation, shelter, food security, law and order, etc. Effective mechanisms for multisectoral collaboration and coordination are therefore necessary to ensure optimized emergency risk management in the health sector. These should be established at national and local levels, wherever possible.
- ♦ *Prepared community.* Communities are always the first to respond to disasters and can play a critical role in meeting emergent health needs. Community resilience can be strengthened by building their capacity to prevent, mitigate, prepare for, respond to, and recover from disasters. Local governments, civil society organizations, and individual citizens all have the potential of contributing to ERM.

Key components of emergency risk management

Prevention, risk reduction, and mitigation

There are few measures taken by the health sector alone that can actually prevent a disaster from occurring. The main example is effective vaccination programmes to prevent outbreaks of diseases, such as measles and yellow fever. Most disaster prevention and risk reduction depend largely on the efforts of other sectors (e.g. structural engineers, urban planners), as well as appropriate government policies, plans, and legislation. The application of effective industry standards and government regulations, for example, can minimize the risk of chemical releases from industrial sites. Adherence to building codes will reduce the risks of structural damage and subsequent deaths and injuries following an earthquake. Appropriate land use can reduce the risks of floods and landslides, while improved residential zoning can minimize the exposure of populations to floodwaters.

The area of conflict prevention is more complex and requires consideration of a broad range of political, social, cultural, economic, and security issues. It is likely that many brewing interstate tensions are prevented from escalating into open conflict, such as Eritrea and Ethiopia over the past decade. Such successes almost always involve multiple players and a variety of factors going well again and again over time. Thus, there is little capacity to weigh the relative importance of each factor and thus develop a precise science of conflict prevention (International Crisis Group 2005).

Disaster risk assessment

Collaboration with other sectors in disaster risk assessment is essential to identifying risks in advance and developing clear strategies to manage them (International Federation of the Red Cross 2006). The health component of a multisectoral risk assessment aims to determine the likelihood and potential public health impact of future disasters. Possible health consequences include direct impacts on people (e.g. injury, disease) or health facilities, and/or secondary effects due to damaged infrastructure (e.g. water and sanitation systems), population displacement, environmental damage, etc.

Classically, risk is considered as a result of the interaction of potential hazards, level of exposure to those hazards, existing community/societal vulnerabilities, and local capacities. This interaction is well represented by the following illustrative formulation:

$$\text{Risk} = \text{hazard} \times \text{exposure} \times \text{vulnerability/capacities.}$$

The first step in the risk assessment is hazard identification and analysis. This includes describing the full range of possible hazards (e.g. natural, technological, biological, and societal), their potential scale, population likely to be exposed, geographic location, and historical record, including their previous health impacts.

Vulnerability analysis attempts to determine the exposure and susceptibility that a given community may have to the identified hazards. For example, a coastal community will have greater vulnerabilities to hurricanes than communities located at a distance from the shoreline. Issues to consider include baseline health and nutritional status, socioeconomic status, physical location and environment, access to healthcare, health knowledge and behaviours, availability of other services and infrastructure (e.g. water, sanitation, transportation), marginalized groups, etc. A review of health infrastructure and programmes should be considered within the analysis, as damage to health facilities can have substantial implications for the community.

An associated assessment of national and local capacities to manage the identified risks is also required. This will allow health professionals, disaster managers and other stakeholders to determine their strengths and weaknesses, and provide an indication of what may be required for capacity development.

Strategies and programmes

Information from the risk and capacity assessments is then used to develop strategies and programmes to reduce the potential impact on public health by the identified hazards. These may include general health system strengthening measures to improve the coverage and effectiveness of existing health services (e.g. vaccinations, training and supervision of staff, improved drug management). They may also include specific health sector interventions that can mitigate the effects of disasters, such as the successful safe hospital programme in Latin America (Pan American Health Organization 2002) and early warning alert and response systems for outbreak control.

The International Health Regulations (IHR) is an international legal instrument that outline obligations and rights of 194 countries to prevent and respond to acute public health risks that have the potential for international spread (WHO 2005). These mostly include epidemics, chemical spills, or nuclear incidents. The IHR aims to limit disturbances to international travel and trade while protecting public health by preventing disease spread. Countries have obligations to report any potential events to the WHO, as well as to strengthen their surveillance and response capacities. The WHO, in turn, provides technical assistance to countries for response and for capacity building, as well as working with its Member States more broadly to ensure global public health security.

Preparedness

The UNISDR definition of preparedness is ‘the knowledge and capacities developed by governments, professional response and recovery organizations, communities and individuals to effectively anticipate, respond to, and recover from, the impacts of likely, imminent or current hazard events or conditions’ (UNISDR 2010). Many emergency organizations also use the related term ‘readiness’ to describe their ability to rapidly and appropriately respond to a disaster.

Sound preparedness clearly arises from an effective risk assessment and is linked to early warning systems. It should ensure that

the required resources and capacities can be rapidly deployed following the onset of a disaster. Clear emergency functions should have been specified in advance and rosters of qualified and experienced staff developed. Stockpiles of essential drugs, equipment, and supplies should be established and maintained, including strong logistics procedures. All emergency staff should be trained in the relevant technical standards, performance standards, and response procedures (Sphere Project 2011). Standard operating procedures should address key administrative, financial, procurement, and communications functions. Coordination mechanisms should be developed in advance, both for improved health sector and intersectoral functioning. Contingency planning may take into account possible scenarios and triggers for response, and further strengthen coordination.

While most preparedness plans will follow an all-hazards approach, some hazard-specific planning may also be required. This is especially relevant for radio-nuclear and chemical incidents, as well as epidemics and pandemics. When planning for conflict-related crises, issues related to protection become especially relevant and should be anticipated and prepared for.

Preparedness and readiness require strong institutional commitments and dedicated budgetary support. Regular exercises and simulations are necessary to test plans and to inform adjustments to procedures. Lessons learned from actual disaster responses should also be fed back into the preparedness plans to ensure that they are better placed to address field realities.

Response

Timely and effective response has the potential to save lives, reduce disability, prevent disease, and contribute positively to the recovery process. The success of the response will clearly be directly related to the effectiveness of preparedness and the associated response plans. Strengthening and reinforcement of both public health (e.g. vaccinations, environmental health) and clinical (e.g. trauma care) services will be required.

Coordination mechanisms should ideally be in existence prior to the disaster, as noted earlier. But in some instances, these mechanisms may be either weak or rudimentary. Wherever possible, existing national coordination mechanisms should be supported and strengthened, with the Ministry of Health taking the lead in the health sector. For disasters requiring an international response, operational agencies may come together under the 'cluster system', which provides a process for joint assessments, planning, promotion of standards, and monitoring and evaluation (Interagency Standing Committee 2013). The WHO is the lead agency for the Global Health Cluster and usually leads the health cluster at country level as well.

Monitoring and evaluating (M&E) the response is a critical step, but is often not well managed. Many factors conspire to make M&E challenging—the acuteness and scale of the disaster, remote and/or austere sites for operations, insecurity, lack of capacity, etc. It is not always possible to document the impact of the response in terms of mortality and morbidity rates, or prevalence of malnutrition. But responding agencies should be able to, at the minimum, document the coverage of the services that they provide, demonstrate that they are meeting the needs of the most vulnerable, and document that they are effectively filling gaps. The requirements of accountability to the affected population(s) demand this attention to M&E.

Recovery

Effective response should lead to more timely and efficient recovery, which should, in turn, lead to improved risk reduction and preparedness, and greater resilience of communities and the health sector. This is central to the so-called build back better approach. Recovery programmes are increasingly informed by post-disaster needs assessments (PDNAs), which provide a measure of loss within each sector and a prioritized plan for recovery and reconstruction (World Bank Global Facility for Disaster Reduction and Recovery 2011).

Following protracted conflicts and disasters, time-limited national transitional health plans may be adopted. These can help the country's health system evolve from a humanitarian model, in which services are designed mainly to provide life-saving services and are provided largely by non-governmental organizations (NGOs) to a developmental model. Liberia provides an impressive example of how a well-designed transitional national health policy and plan can support the gradual expansion of health services over time, following a period of protracted health system dysfunction due to years of conflict.

Organizing disaster and emergency risk management

National and regional levels

Many countries have established National Disaster Management Authorities (NDMAs) to oversee the design and implementation of disaster and emergency risk management efforts. These authorities usually have responsibility for leading risk assessments, developing disaster risk reduction and mitigation strategies, strengthening preparedness, and leading response and recovery efforts. In some high-profile disasters, other government ministries or departments may assume the lead role in managing the response, for example, the Prime Minister's office. A number of countries, such as Pakistan, have also extended disaster management authorities to provincial and district levels.

The capacities of and resources available to such agencies vary considerably. Countries such as Indonesia have invested substantially in developing national systems, while others have been far less proactive or successful. Nonetheless, it is important for Ministries of Health to engage vigorously with NDMAs to ensure that health is well positioned within national disaster management policies, plans, and arrangements. The impact of disasters is perhaps best defined by their effects on the public's health, although this may not always be obvious to some disaster managers. Ministries of Health should establish their own national programmes for health emergency risk management and ensure that health is well represented in national dialogues and initiatives.

Because the effects of disasters often span borders (e.g. the 2004 Asian tsunami), regional bodies and initiatives have also been established to promote coordination and collaboration on ERM. ASEAN has established a coordinating centre for humanitarian assistance and disaster management, the League of Arab States has developed an Arab Strategy for Disaster Risk Reduction 2020 (ASDRR), and the Organization of American States and League of Arab States have developed programmes to plan for, prepare for, and coordinate responses to crises.

International level

There is a broad range of bodies involved in ERM and disaster response at the international level, including UN agencies, the Red Cross and Red Crescent Movement, NGOs, donors, governments, and, increasingly, the military and private sector. The UN's Office for the Coordination of Humanitarian Affairs (OCHA) plays an important role in convening the major relief agencies and coordinating international humanitarian policy, planning, and relief efforts. The UN Interagency Standing Committee (IASC), chaired by OCHA, is the main international body representing the major relief agencies and plays a central role in setting global policies and establishing procedures for international response. The WHO is the main health agency on the IASC.

Following suboptimal responses to major disasters in Haiti and Pakistan in 2010, an IASC-led process of humanitarian reform was initiated in 2011 to improve the leadership, predictability, coordination, and effectiveness of emergency response. Known as the Transformative Agenda, this process also emphasizes accountability to affected populations as one of the key principles guiding humanitarian action.

The medical relief agency MSF plays a special role in international emergency response. Although it stands outside some of the formal coordination mechanisms at international level, it has the largest operational field presence of any such agency. It has resources and capacities that are matched by no other medical NGO.

Public health needs

Oxygen, water, and food remain the essential priority human needs in almost all settings including the most acute of hardships. The initial handbooks overviewing the public health priorities in high-mortality, low-resource settings remain as relevant today as when they were written (CDC 1992; MSF 1997). Most were lacking in some areas now better appreciated, with obstetric care being perhaps the most dramatic example. Usually those handbooks defined an emergency in terms of a doubling or quadrupling of the baseline mortality rate. In settings of extreme hardship, those displaced and whose livelihoods and social order are disrupted will generally continue to die and suffer from the same ailments they experienced before the crisis but at a higher rate. In some categories of disasters such as natural disasters like earthquakes and floods, death profiles are briefly but dramatically altered but prolonged elevated mortality is rare. Thus, in the most typical disruption and displacement scenarios, acute respiratory infections, diarrhoea, and in some places malaria, dominate the prevention and treatment priorities. Yet, these kinds of crises, with mortality rates elevated fourfold or more, are accounting for a smaller and smaller fraction of all humanitarian aid. Most aid workers today can work an entire lifetime and never see the dramatically elevated mortality of ten or 20 times the baseline rates seen repeatedly in the 1960s through the Rwandan Crisis of 1994. For example, if we use the threshold of 2 per cent of the population dying each month (ten times the highest of baselines) in a population over 100,000 people to define a humanitarian catastrophe, a review of both published and unpublished mortality reports suggests that from 1979 to 1994, there was such a catastrophe on average every 2 years, but none have been reported since that time (Roberts 2013). The camp-based relief setting has also become rare, forcing

relief agencies to work in cities and with existing government institutions.

This change away from relief typified by water and food delivery and lifesaving primary healthcare approaches is being driven by four forces: the global transition from a disease burden profile typified by acute infectious illness to one dominated by chronic diseases, more aid funding and fewer acute wars inducing a lower threshold of what is considered a humanitarian crisis, changing motivations, and the rise of the rights-based framework within humanitarian relief.

Transition from acute infectious diseases to chronic conditions

The epidemiological transition occurring in developing countries has been well documented. For example, Lopez et al. contrast the causes of death among adults in various regions based on 1990 and 2001 data respectively (Fig. 11.10.1) (Lopez et al. 2006). Over those 11 years, the non-HIV infectious disease adult death rates declined markedly in Latin America and the Caribbean, the Middle East and North Africa, East Asia and the Pacific, and South Asia. In each locality, this reduction in infectious disease death rates corresponded with lower overall adult mortality. Only in the post-Soviet Europe and Central Asia region and Africa did adult mortality rise over this period; in the former, primarily from cardiovascular diseases and unintentional injuries, and in Africa primarily from HIV. In Africa, overall mortality still decreased over this period because of dramatic reductions in infant and child mortality.

The impact of this epidemiological transition was evident in recent crises in Bosnia, Kosovo, and Iraq, where Ministries of Health and aid agencies were confronted with morbidity profiles dominated by non-infectious diseases. For example, among Kosovar refugees in Macedonia treated by the Red Cross in emergency clinics, hypertension, diabetes-related issues, and dialysis were dominant needs (Gardemann 2002).

Similar experiences were noted in recent crises in Northern Africa (e.g. Libya), the Middle East (e.g. Syria), and Asia (e.g. Indonesia).

Adding to this need to transition medical preparedness for emergencies is the growing appreciation of HIV as a non-fatal chronic condition. An estimated 5 million Africans regularly received antiretroviral drugs (ARVs) in 2011 (WHO et al. 2011), a fraction of the total number of Africans who are HIV positive. As most of the world's protracted conflicts are in Africa and a disproportionate number of humanitarian operations occur there, planning for the chronic disease support aspects of HIV needs to be part of the humanitarian public health portfolio (O'Brien et al. 2010).

For the 2010 presidential elections in Côte D'Ivoire, the agency ICAP anticipated political unrest and provided 3 months of advance supplies of ARVs to almost everyone in the country on the therapy. Widespread violence did rock the country after the elections and in some areas government health facilities were closed for weeks. A non-random but widespread assessment after the crisis suggested that people appropriately managed their personal drug supplies and there were almost no ARV supply ruptures from the crisis (Twyman 2012). This kind of new chronic disease programme planning will undoubtedly become more widespread within the relief community.

Fig. 11.10.1 Death rates by disease group and region in 1990 and 2001 for adults aged 15–59 years. *Includes respiratory infections. Cause-specific death rates for 1990 (estimated from Murray, C.J.L., Lopez, A.D. (eds.) *The Global Burden of Disease: A Comprehensive Assessment of Mortality and Disability from Diseases, Injuries and Risk Factors in 1990 and Projected to 2020*. Cambridge: Harvard University Press, 1996) might not be completely comparable to those for 2001 because of changes in data availability and methods, plus some approximations in mapping 1990 estimates to the 2001 regions East Asia and Pacific, South Asia, and Europe and Central Asia. For all geographical regions, high-income countries excluded and shown as single group at top of graph. The geographical regions therefore refer to low- and middle-income countries only.

More aid and fewer high-intensity conflicts

Spending on humanitarian assistance has increased dramatically in recent decades. The 2011 Arab Spring aside, there has been a dramatic downward trend in the numbers of conflicts since the end of the cold war. The number of ongoing conflicts is estimated to have declined by over 50 per cent since the collapse of the Soviet Union (Gleditsch et al. 2002). Garfield estimated the global populations affected by conflict over time, disaggregated by levels of conflict intensity (Fig. 11.10.2) (Garfield et al. 2012). While the numbers of people living in the two highest levels of conflict intensity have reduced dramatically over the past 10–15 years, the numbers living in post-conflict environments have dramatically increased. Nonetheless, worsening violence and major population displacements over the past 1–2 years in Syria, the Central African Republic, and South Sudan call into question the certainty that this positive trend of diminishing violent crises will continue in the years to come.

According to Global Humanitarian Assistance, formal humanitarian assistance spending increased fourfold from 1990 to 2010 (United Nations Children's Fund 2013). Thus, the world is spending more money and delivering more humanitarian programming to fewer people in the most acute settings. Unfortunately, however, more aid is being taken up by the increasing numbers of people requiring relief after natural disasters, and to a lesser extent, technological disasters such as the Fukushima nuclear

meltdown in 2011. This has the effect of lowering the mortality prioritization with regard to what is considered a humanitarian crisis. It also means since much if not most humanitarian spending is in post-conflict settings, that humanitarian assistance is now inseparable from development work.

Changing motivations and the rights-based framework

Aid meant to induce development may be different in nature from humanitarian aid designed to prevent deaths and suffering in the short term. Donors are continuing to place increasing emphasis on sustainability of humanitarian interventions and demanding local participation and empowerment. These are natural changes in perspective that match a transition from death aversion to development priorities. A few NGOs such as MSF maintain a philosophy that they work primarily to reduce death and suffering but most others now hold long-term impact and sustainability as central objectives. This creates several new conditions for relief work. Many relief efforts in the 1980s and 1990s defined success by the lowering of the crude mortality rate (CDC 1992). This is rare today. Sustainability efforts usually require training and supporting local officials and institutions, committing to multi-year engagements, and monitoring changes in behaviours. These require different skills from those prevalent in relief agencies in the twentieth century. Reconstruction activities following

Fig. 11.10.2 Populations living in areas of conflict or post-conflict areas, 1956–2007.

Reproduced from Garfield, R.M. et al., Changes in size of populations and level of conflict since World War II: implications for health and health services. *Disaster Medicine and Public Health Preparedness*, Volume 6, Issue 3, pp. 241–6, Copyright © 2012, by permission of Cambridge University Press.

earthquakes and tsunamis often employ many times more construction and economic experts than health professionals and epidemiologists.

In tandem with this shift in focus from just averting deaths, has been the rise of a rights-based approach to programming. UNICEF defines a human rights-based approach as ‘a conceptual framework for the process of human development that is normatively based on international human rights standards and operationally directed to promoting and protecting human rights’ (UNICEF 2013). This framework, while not fundamentally contradictory, is very different in focus and in programme implications from the ‘public health’ approach of the last century’s relief operations (CDC 1992; MSF 1997). This public health approach concentrated on how the relief community could reduce the most deaths and suffering with the assets available. This manifested in specific interventions like measles immunization, latrine construction, or primary health-care clinics which brought broader benefits at low costs.

The rights-based approach has the advantage that it more readily encompasses issues like psychological suffering which are harder to measure, and values such as that girls should have equal chances for advancement as boys. But, the term ‘normatively based’ in the UNICEF definition is not well defined or constant. For example, UN resolutions or agency position statements often stress the need to have child re-unification programmes where benefit is difficult to demonstrate (Ager and Metzler 2012). In the public health approach the benefits and the cost-effectiveness of programmes are more readily established, and new ideas can be compared with established programmes. Rights-based programming, in contrast, has no equivalent incentive to demonstrate

cost-effectiveness and in fact is more driven by the strength of resolutions or declarations. Thus, if one wants to advocate for the value of counselling rape victims, in a rights-based framework it would be more efficient to attempt to pass a UN resolution than to evaluate the effectiveness of programmes in the field. With the public health approach, the opposite would be true.

In summary, humanitarian public health needs have broadened as the clientele served has begun to span a broader range of development levels, as the need to support people with chronic conditions including HIV has become more important. This may be an indication that the humanitarian endeavour has worked over the past half century. A Biafra-like scenario, where half the population died in a 4-year period, is rare today. Thus, the world’s growing sources of compassion and aid can serve more than just those on the verge of death.

New developments for the twenty-first century

A host of new developments make it likely that relief work in the middle of the twenty-first century will look little like efforts in Biafra and South East Asia the century before. The advances of the past decades that will likely expand in the future can be considered in three broad categories: political trends, new approaches, and new technical advances. These categories interact with and influence each other, with technical advances often creating the potential for new orderings of social organization. While not comprehensive, this section seeks to imagine the likely changes to come in the field of humanitarian response.

Political trends

The melding of political and humanitarian agendas

National governmental political agendas and humanitarian relief have never been completely independent. In 1919, the US Congress formed the American Relief Administration (ARA), supposedly an independent NGO-like entity, headed by future President Herbert Hoover, to act as an independent famine relief mechanism in Europe in the years following the First World War (Fisher 1927). Oxfam, among the most famous of NGOs for its politically neutral funding sources, was formed in large part to lobby the British government to loosen the Allied blockade of occupied Europe (Oxfam n.d.). MSF co-founder Bernard Kouchner later became the French Minister of Humanitarian Affairs and the Foreign Minister, allotting funding for his creation, MSF. That humanitarian and political interests overlap is not completely unhealthy if in a democracy the populace is privately choosing to fund humanitarian ventures while simultaneously influencing the priorities of their government to do the same. On the other hand, countries are often in open competition with each other, and the linking of aid to enhance economic, military, or political competitiveness would be antithetical to the humanitarian endeavour. Two documents have attempted to keep humanitarian aid 'neutral' in the eyes of combatants and beneficiaries over the last part of the twentieth century.

Both the Third Geneva Convention of 1949 and the Red Cross Code of Conduct, to which most NGOs and the UN aspire to adhere, actively encourage the separation of humanitarian endeavours and self-interested agendas of individual states. The fourth tenet of the non-binding Red Cross Code of Conduct explicitly states, 'We shall endeavour not to act as instruments of government foreign policy' (International Federation of Red Cross and Red Crescent Societies n.d.). The ICRC and MSF are particularly famous for keeping political and military forces at arm's length even during the acute phases of crises. For example, during the 1992 crisis when Kurds fled northern Iraq but were not allowed into Turkey, the MSF refused to move in public or cooperate with any military personnel carrying a weapon. Many military personnel, including the British and American forces who had just invaded Iraq and were thus belligerents in this conflict, operated within the displaced community without weapons so as to work with MSF and other NGO personnel. Thus, until 2001, while funding influenced where relief went and what kinds of relief efforts were funded, an honest effort was made on the part of most donors and most international NGOs to not undertake patently political activities to advance the agenda of one country.

Nonetheless, a remarkable change in the landscape of humanitarian assistance has been the melding of political and humanitarian agendas after the terrorist attacks on New York City on 11 September 2001. Beginning with the invasion of Afghanistan, this narrowing separation of political and humanitarian ventures was often ignored or blurred. In October 2001, US Secretary of State Colin Powell addressed leaders of the American NGO community referring to their organizations as 'force multipliers' (International Federation of Red Cross and Red Crescent Societies n.d.). In Afghanistan, US humanitarian aid was openly discussed as a military tool for winning hearts and minds. In May of 2003, USAID Administrator Andrew Ntasia told the American NGOs that they needed to do a better job of advertising that the goods

and services they provide to the Afghan people were coming from the US government. He told the American NGOs that they were an 'arm of the US government' (Klien 2003). Military activities such as distributions and school construction often made it unclear what was being done by combatants and what was being done by NGOs (Falconer 2009). MSF, who had been working in Afghanistan for 33 years, was forced to pull out there and in Iraq after their aid workers were targeted for assassination (Katz and Wright 2004). This blurring of aid and political agendas was again demonstrated when the Central Intelligence Agency hired a physician to conduct a sham vaccination campaign in Pakistan as part of the hunt for Osama Bin Laden in 2011 (Roberts and VanRooyen 2013; Rubenstein 2013).

The responses to natural disasters are not devoid of political overtones or agendas either. Following the 2005 tsunami in a largely Muslim area of the Pacific, the US Secretary of State called the disaster a 'wonderful opportunity' for the United States (Anonymous 2005). Preferential responses to former colonies and near neighbours appear to be an inevitable aspect of bilateral giving following natural calamities.

Since 2003, the number of annual incidents of violence against aid workers has doubled globally (Jackson 2012). It is not yet clear how the active blurring of humanitarian endeavours and military and political strategizing will play out in other non-conflict settings. There is little doubt that the humanitarian space available in politically tense settings will continue to diminish. New overt military and humanitarian blending during the Arab Spring of 2011, particularly in Libya, may create models of humanitarian and military blending less concerning than those seen in Afghanistan and Iraq and more acceptable to the affected populations. While the 1999 NATO bombing of Kosovo, and to a lesser extent, conflicts in Bosnia, Somalia, and Cambodia, set the stage for such transparent coordination between specific national agendas and humanitarian actors, that coordination has reached a new level of openness and complexity in recent years.

Humanitarian accountability

While aid agencies and the Red Cross Code of Conduct have always purported to support local empowerment and accountability of aid deliverers to beneficiaries and donors alike, many new developments have made that aspiration more common. The third edition of the Sphere Standards (Sphere Project 2011), perhaps the most widely followed guidelines for humanitarian practice, has an expanded emphasis on local participation and accountability to beneficiaries. In 2010, the UN passed an 'Accountability Framework' which may or may not result in more cost-efficient services on the ground, but certainly contributes to an international focus on recording transparently what is achieved by aid efforts and at what cost (UN 2010). Likewise, in 2011, the IASC developed an operational framework on how to ensure accountability to affected populations in humanitarian emergencies which is widely cited among humanitarian players (IASC 2011). Thirdly, the rise of wealthy, highly functional governments in all regions of the world raises the expectations of aid delivery procedures. For example, in 2003, India became a net creditor to the IMF and the WFP (Bijoy 2011). The rise of local NGOs as a primary international delivery mechanism, the prevalence of social networking, and the economic downturn in post-2008 Europe and North America all point toward a future where local and

more players have a larger role in what aid is provided and how it will be disbursed.

New approaches

The growing appreciation of local capacities to provide exacting technical services combined with technical advances and greater emphasis on accountability, have paved the way in the past decade for exciting new ways of delivering aid. Among these are the following.

Home-based treatments

In the 1980s, the promotion of ORT was championed aggressively by the UN and aligned agencies because it was seen as a way to overcome the primary barrier to successful treatment of acute illness, namely early detection and treatment. The logic was that if people did not have to go through the effort of transporting the patient and their things to a medical facility, far more people would get treated. This was partially the logic behind the bare-foot doctors programme in post-revolution China and a variety of other initiatives such as mobile clinics (Gish and Walker 1977).

Over the past decade, ambitions to provide antiretroviral treatments in areas of modest medical infrastructure and limited resources have resulted in a variety of models for drug distribution and patient monitoring using community or patient volunteers, or paid community health workers. The evidence suggests that patient management and monitoring schemes that are not physician based, where the monitoring occurs closer to the community level, are associated with better patient retention and survival (Callaghan et al. 2010). In focused settings of high malaria transmission, home-based treatment of fever has been shown to be an effective life-saving approach (Kidane and Morrow 2000).

In emergency settings, no home treatment strategies have received more attention or inspired as much enthusiasm as home therapeutic feeding. Home therapeutic feeding usually involves training and equipping mothers of malnourished children to cure the child at home with a nutritious ready-to-use food such as eeZeePaste NUT® or Plumpy'Nut® which come precooked and are resistant to bacterial growth. These ready-to-use home treatment products cut down on attrition in feeding centres, are a less expensive means for treating moderately malnourished children, and have been shown to be highly effective in field trials (Patel et al. 2005).

Crowd sourcing and mobile phones

The widespread availability of mobile phones and social media has made it possible to have the whole population participate in the monitoring of crises. One of the most well known of these efforts is the Ushahidi platform, formed during the violent period following the 2008 Kenyan elections (Ushahidi n.d.).

Perhaps the most dramatic application of the Ushahidi platform was in the February 2010 Chilean earthquake. The 8.8 magnitude quake was followed by a series of aftershocks that damaged thousands of buildings and ultimately killed an estimated 521 people. Within 48 hours of the initial quake, an Ushahidi–Chile platform was established and a team of graduate students in New York began mapping press reports and text messages to create a picture of damage and where people were trapped. One hundred 'incidents' were mapped in the first day of operation and 700 were mapped by the end of 3 days. In the weeks that followed, the

Ushahidi platform updated local press members and the general public about food distributions, dangerous buildings, the occurrence of looting, and the progress of children re-attending school (Carlsen et al. 2011). Crowd sourcing strategies have also been used to inform Chinese authorities about acute situations in the aftermath of the Szechuan earthquake, to map the occurrence of sexual violence in Syria, and to map unsafe areas following the Japanese tsunami of 2011.

Mobile phones by themselves are allowing for some exciting innovations. Somalis affected by conflict have received humanitarian aid in the form of phone credits which can be used to purchase goods in local shops (Global Communities n.d.). Mobile phones have been given out in DR Congo with solar chargers to enable communities to call local authorities, the UN, or human rights workers when human rights abuses are taking place (Guinote 2012). Many of these initiatives are exploratory and controlled trials will be needed to establish such procedures as effective protective investments. One particularly interesting application of mobile phone use took place in the weeks following the 2010 earthquake in Haiti. The largest mobile-phone carrier sent out a signal detecting active SIM cards every day in relation to the nearest mobile-phone tower. They were thus able to record the position of 1.9 million active phones for 42 days before and 158 days after the earthquake. They estimated that 630,000 people in Port-au-Prince left the capital in the 19 days following the earthquake (Bengtsson et al. 2011). It is likely such mobile-phone tracking will become increasingly utilized in the years to come.

Monetary aid

As part of the promotion of local and beneficiary empowerment, providing aid that allows beneficiaries to set their own priorities has become increasingly popular. The example of giving displaced Somalis mobile-phone credit was discussed earlier. But, giving cash directly to beneficiaries in lieu of rations or material goods has several advantages. People are more likely to end up with what they want and the transfer costs are far lower. It has the potential to support the local economy including creating incentives for future increased local food production. It potentially has downsides such as driving local inflationary pressures and exposing people to increased risks of exploitation and extortion. A recent comprehensive review generally weighs the upsides as being greater than the downsides but suggests that implementers will need to choose the contexts carefully and develop methods for monitoring the success of direct cash assistance (Harvey 2007).

Closely related to monetary aid is the distribution of credit vouchers or coupons. Sometimes these have a specific purpose such as paying for school fees or uniforms. The most common flexible distribution is non-food item (NFI) or food item fairs where a select collection of vendors selling at predetermined prices gather in one place and beneficiaries with coupons spend their coupons at this one place and time. This system has the advantages of giving beneficiaries choice over the aid items they receive, it supports local markets, and leaves beneficiaries less open to local extortion. A recent analysis of such a NFI fair aimed at recently displaced populations in South Kivu Province, DR Congo found that local authorities missed most IDPs when constructing vulnerable lists and included many locals. At the end of the NFI distribution process, the NFI 'vulnerability score' as defined by UNICEF was unchanged by the distributions (O'Keeffe and Zdravetz 2012). As

with so many new practices, implementation and evaluation procedures will need to be developed locally to match each context in order to maximize the efficiency of distributions via fairs and similar voucher systems.

New technical advances

A host of new technical advances or tools also create the potential for transformative advances in humanitarian relief in this century. Some technologies, such as the Global Positioning System (GPS), are so essential to relief efforts at present that it is hard to realize that the technology was almost non-existent 20 years ago. It is likely to evolve as a tracking tool for people, goods, and vehicles. One-dollar GPS transmitters will likely result in the tracking of individual cases of vaccines and drugs, and curb looting of warehouses by armed groups. Eye and fingerprint scanning technologies are reducing ration theft and false registrations across the globe. Advances in medicine, in diagnostic techniques, or protective devices such as long-lasting impregnated bednets, are constantly changing the practice of humanitarian relief. Some of the more promising new technical and medical breakthroughs are highlighted here.

Satellite imagery and remote sensing has already changed humanitarian practice. UNHCR has used satellite images to count people moving from Darfur into Chad. For years, remote sensing has been used to predict crop failure and crop yields. The destruction of villages in Darfur and DRC has been documented with before and after remote images. But lately, satellite imagery has been used to undermine the impunity brought by national sovereignty. For example, in 2006, the government of Zimbabwe cleared the major cities of people living on land for which they did not have deeds. It is estimated that 700,000 people had their homes destroyed (Tibaijuka 2005). Satellite images from before and after were the primary evidence of governmental wrongdoing and of the magnitude of the forced displacement. At the time, almost no international press was permitted to operate in Zimbabwe.

Cloud computing and Internet collaboration hold potential for a host of new ideas and innovations that may assist those responding to emergencies. Groups like Hackers for Humanity attempt to channel the efforts of Internet talents to charities (Hackers for Humanity n.d.). A variety of efforts to solve 'humanitarian problems' have been addressed by crowdsourcing for a solution. The degree to which these efforts change the lives of people affected by crises is difficult to assess. Some more focused software or cloud-based advances are now widely used and are filling specific niches. For example, Martus is a free online resource that allows human rights NGOs to store, access, and process data via a cloud mechanism that leaves no data on the computer used for entry. All data is encrypted and it is advertised that only users with their own passcode can access the data stored on multiple servers on multiple continents (Martus n.d.). Niche tools such as Martus are likely to increase the efficacy and safety of human rights and humanitarian work in the decades to come.

Internet accountability mechanisms: Google Earth and the Internet are allowing for greater accountability of aid from the perspective of small private donors. A model held up as innovative but already being reproduced is that of Charity Water. Charity Water does not directly implement water supply and sanitation projects, but instead subcontracts with local operational partners to turn Western private donations into water and sanitation

infrastructure (Charity Water n.d.). Charity Water provides donors with the latitude and longitude of the specific things people have paid to have built so that over time they can see if indeed a well was built or public tap installed, and they can monitor if it continues to be used over time. They even install monitors so that donors to a specific project can see at any given moment if water is flowing from it. While not all aid is remotely visible, this process of linking donors to beneficiaries visually or by social media will likely grow over time and the process of humanitarian assistance will be better for it.

Conclusion

The twenty-first century is likely to see an ever growing humanitarian movement that will become more focused on economic, emergency preparedness, and developmental issues. Aid will be more politicized, while simultaneously more locally controlled and with greater accountability for implementation. The post-Biafra humanitarian endeavour has been associated with a dramatic decline in extreme episodes of excess deaths associated with crises and the new face of humanitarian relief, which often looks a lot like development work of old, has largely been built on the successes of twentieth-century humanitarian relief.

Principles of public health emergency response for acute environmental, chemical, and radiation incidents

Naima Bradley, Jill Meara, and Virginia Murray

Introduction to principles of public health emergency response

Acute environmental, chemical, and radiation incidents and emergencies can have significant effects on people's health, including loss of life. New threats reveal new challenges for managing the health risks and effects of emergencies. Deaths, injuries, diseases, disabilities, psychosocial problems, and other health impacts can be avoided or reduced by skilled disaster management involving health and other sectors.

Incident and emergency risk management for health refers to the systematic analysis and management of health risks, posed by incidents and emergencies, through a combination of:

- ◆ Hazard and vulnerability reduction to prevent and mitigate risks.
- ◆ Preparedness.
- ◆ Response.
- ◆ Recovery measures.

This is summarized in Fig. 11.11.1. Public health services and expertise have a vital role in reducing harm and saving life at every stage in this cycle.

The traditional focus of the health sector has been on emergency response. The challenge is to broaden the focus of incident and emergency risk management to a more proactive approach which emphasizes prevention and mitigation, and the development of community and country capacities to provide timely and effective response and recovery. Resilient health systems based on primary healthcare at community level can reduce underlying vulnerability, protect health facilities and services, and help to scale-up the response to meet the wide-ranging health needs.

Examples of natural, biological, technological and societal hazards that can put the health of vulnerable people at risk and cause significant harm to public health include:

- ◆ Natural: earthquake, landslide, tsunami, cyclone, flood or drought.
- ◆ Biological: epidemic disease, infestations of pests.
- ◆ Technological: chemical or radiological releases or contamination, transport crashes.
- ◆ Societal: conflict, stampedes, acts of terrorism.

Emergencies and other crises may cause ill health directly or through the disruption of health services, leaving people without access to healthcare in times of emergency. They also affect basic infrastructure such as water supplies and safe shelter which are essential for public health.

International consensus views disasters as barriers to progress on the health-related Millennium Development Goals (MDGs), as they often set back hard-earned development gains in health and other sectors. One United Nations instrument that takes forward the emergency and disaster agenda is the *Hyogo Framework for Action 2005–2015: Building the Resilience of Nations and Communities to Disasters* (United Nations Office for Disaster Risk Reduction 2007). This 10-year plan, which will be extended in 2015 for the next 20–30 years, focuses on making the world safer from natural hazards and other emergencies. It identifies five priorities for action which are:

- ◆ Governance: organizational, legal, and policy frameworks.
- ◆ Risk identification, assessment, monitoring, and early warning.
- ◆ Knowledge management and education.
- ◆ Reducing underlying risk factors.
- ◆ Preparedness for effective response and recovery.

Fig. 11.11.1 The integrated emergency management cycle.

Progress has been made at global, regional, national, and community levels, but countries' capacity for risk reduction, emergency preparedness, response, and recovery remains extremely variable. The 2007 World Health Organization (WHO) global assessment found that less than 50 per cent of national health sectors had a specified budget for emergency preparedness and response (United Nations Office for Disaster Risk Reduction 2007). Factors affecting capacity included:

- ◆ Weak health and disaster management systems.
- ◆ Lack of access to resources and know-how.
- ◆ Continuing insecurity due to conflict.

A number of high-risk countries have strengthened their disaster prevention, preparedness, and response systems; in some countries, the health sector has led initiatives developing multisectoral approaches to emergency risk management. Multisectoral working is needed to protect the health of the population during and after a major incident or emergency. Wider determinants of health such as water, sanitation, nutrition, and security also need to be adequately addressed. Essential infrastructure such as communications, logistics, energy and water supplies, emergency services, and banking facilities need to be protected through multisectoral working to ensure the continuity of health services.

This chapter, following from Chapter 11.10 in this volume, considers the various stages of an emergency response and the role of public health at each stage. Case studies are used to illustrate the principles described. Of note is the importance of emergency responders at the scene to save life and protect people (including the emergency responders).

This chapter addresses the following:

- ◆ *Local command and control management arrangements for emergency response:* including the local emergency response arrangements and how they interact with international obligations such as the International Health Regulations from the WHO (see Chapter 11.10).

- ◆ *Exposure and risk assessment:* in any incident response it is essential to assess exposure, as soon as possible, to members of the public, workers, and responders using biological or environmental monitoring or modelling. This will allow assessment of health risks to exposed people and define further environmental and people sampling and modelling to refine risk assessments. There are significant differences in exposure assessment methods between chemical and radiation incidents.

- ◆ *Countermeasures for public health protection:* countermeasures are important to ensure that advice that is given early enough to be effective to reduce exposure, even at the early stages of an incident when little is known. Countermeasures are usually advised by public health professionals in conjunction with their partners in response. Countermeasures are broadly similar for all hazards and include decontamination, sheltering, evacuation, specific antidotes, and medical treatments. The chapter touches on mechanisms of recovery and return to normal.

- ◆ *Public reassurance in emergencies and incidents:* it is essential to have clear messages for information and reassurance to cover both affected and unaffected members of the public. These need to build trust in the systems that have been invoked to protect the public.

- ◆ *Follow-up of affected populations* is often essential. Approaches on how to undertake appropriate follow-up of affected populations including ongoing care and epidemiological follow up are discussed in the context of the Public Health England health registers protocol.

- ◆ *Identify and publish the lessons learned* and examine the importance of sharing learning to decrease the chance of an incident reoccurring and to identify lessons to improve emergency preparedness, response, and recovery.

- ◆ *Conclusion:* including evidence and research gaps and future challenges.

- ◆ *Additional sources of information.*

Planning for an effective response: legislative background

Developing and testing local, regional, and national emergency plans is key to an effective emergency response. These plans should be tailored to address the most important risks to health from natural disasters, man-made accidents, and malicious attacks. At national level, the UK government monitors the most significant potential threats through its National Risk Assessment (NRA). This is a confidential assessment conducted every year, covering a 5-year time horizon. In 2013, the National Risk Register (NRR), the public version of the NRA, which identifies the highest priority emergency risks taking into account both likelihood and impact, added a new risk to the register, the risk from wildfires (Cabinet Office 2013).

The NRR and relevant local risk registers will identify the impact of emergencies (e.g. fires, explosions, and major releases) from major industrial sites as a significant risk. The European Union (EU) Seveso Directive's main aim is to prevent and mitigate the effects of emergencies at approximately 10,000 sites across Europe. A new Directive on the control of major accident hazards

involving dangerous substances (known as ‘Seveso III’), published in 2012, to be implemented in the United Kingdom by 2015 amends the scope of the legislation and has new requirements for public participation and better access to information about risks from activities at certain industrial sites.

Case study: the UK Civil Contingencies Act and Control of Major Accident Hazards Regulations

A key piece of emergency planning legislation is the Civil Contingencies Act 2004 (CCA); its principal objective is to ensure consistency across all government departments and agencies, whilst setting clear responsibilities for frontline responders at a local level. The CCA defines two categories of organizations: category 1 responders such as emergency services, local authorities, health bodies, and government departments are subject to the full set of civil protection duties. The primary role for category 2 organizations is to cooperate and share relevant information with category 1 responders. Examples of category 2 responders are utility companies and transport providers. Local Health Resilience Partnerships (LHRPs) have been created to provide strategic forums for joint planning for emergencies in the new health system. They will support the health sector’s contribution to multi-agency planning through Local Resilience Forums (LRFs).

Three elements are identified in the definition of civil emergency under the CCA: serious damage to human welfare, the environment, and national security.

Local risk registers and plans are needed to reflect unique local characteristics; for example, coastal flooding will only affect certain areas of the country. Most local risks need to be considered in a multi-agency setting; this is done through LRFs which include representatives from local emergency responders as well as public, private, and voluntary organizations. LRFs publish local risk registers and develop and exercise local emergency plans.

In the United Kingdom, the Control of Major Accident Hazards Regulations 1999 (COMAH), as amended in 2005, and the Control of Major Accident Hazard Regulations (Northern Ireland) 2000 implement the requirements of the Seveso Directive (currently Seveso II). They aim to prevent and mitigate the effects of major incidents involving dangerous substances, therefore they cover high-risk sites such as those in the chemical and petro-chemical sectors. COMAH defines two types of sites called ‘top tier’ and ‘lower tier’. For the higher-risk ‘top tier’ sites, local authorities will prepare and test emergency plans addressing the consequences of foreseeable major accidents from these sites.

Case study: Seveso accident

In 1976, there was a major incident at a chemical plant manufacturing pesticides and herbicides near the town of Seveso, Italy (Pesatori et al. 2003). The resulting cloud covered an 18-square kilometre area. Ten days after the accident, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) was confirmed as one of the main components of the toxic cloud. TCDD, the most toxic dioxin, is toxic by ingestion and inhalation. The International Agency for Research on Cancer classifies TCDD as a chemical which can cause cancer in humans.

The dispersal of TCDD resulted in widespread contamination of land and vegetation. Although no fatalities were reported,

193 cases of chloracne were observed, mainly in children who were exposed outdoors in the immediate aftermath. Several hundred people were evacuated and approximately 2000 were treated. Studies of the long-term impacts of this exposure are still under way.

This accident prompted the adoption of legislation aimed at the prevention and control of such accidents.

Nuclear licensed sites

Many countries have separate arrangements for regulation of ionizing radiations and the nuclear industry. For example, in the United Kingdom, emergency preparedness duties with respect to nuclear sites are described in the Radiation (Emergency Preparedness and Public Information) Regulations (REPPiR) 2001. As for the COMAH regulations, the REPPiR regulations take precedence over the CCA in relation to specialized emergency preparedness and response but CCA guidance applies in areas not covered by these regulations.

The Office for Nuclear Regulation identifies the emergency planning zones (DEPZ) for sites where there could be an off-site radioactive release. There is a legal requirement for local authorities to prepare plans for responding to an off-site nuclear emergency, including within the DEPZ.

International Health Regulations

The International Health Regulations (IHR), agreed by the World Health Assembly in 2005 and revised in 2007 (WHO 2008), were introduced to protect the world from global health threats. The need for such an internationally binding instrument was identified following the emergence of severe acute respiratory syndrome in 2003, which demonstrated how quickly a new disease could spread. As a result, 196 countries acknowledged a responsibility for collective action against infectious diseases, and food and environmental contamination, deemed to be public health emergencies of international concern. Member states are responsible for developing, strengthening, and maintaining the capacity to detect, assess the risks of, and respond to public health emergencies. Furthermore, countries are required to notify the WHO of these threats through their designated National IHR Focal Point within 24 hours.

The European Commission identified a need to ensure consistent and coordinated implementation of the IHR by the EU Member States and address gaps in emergency planning, response, risk assessment and management, and risk communication identified during cross-border emergencies such as the pandemic influenza (H1N1) in 2009/2010. The Commission also acknowledged that cross-border arrangements needed to be strengthened to deal with environmental incidents such as the volcanic ash cloud in 2010. As a result, the EU Decision on serious cross-border threats to health was published to strengthen the EU’s capabilities to deal with threats of biological, chemical, and unknown origin (European Commission 2013). Extreme weather and other natural events such as heat waves and cold spells are included in the scope of the EU Decision but radiological or nuclear health threats are not as they are already dealt with by the Euratom Treaty establishing the European Atomic Energy Community.

Emergency response framework

Rapid implementation of collaborative arrangements described in the emergency plans, coordination, and communication are the key to successful management of an emergency. Most emergencies are handled at the local level by emergency services and local responders. Established local early alerting mechanisms will notify other agencies and provide support and advice. For major incidents, the multi-agency coordination mechanism is managed through a 'command and control' flexible framework involving strategic, tactical, and operational levels. The gold command will develop the strategy to manage the many aspects of an incident, the silver level will identify how to implement the strategy, direct the operations, and monitor progress, and the bronze level will carry out the tactical decisions and involve the physical deployment of resources. In the initial phase of an incident, the local ambulance service, fire service, and/or police will usually be the first blue-light services on the scene. They provide the bronze level management of the incident including setting up cordons, fighting fires, and treating casualties.

The multi-agency coordination groups will be led by the most appropriate emergency responder. For example, the police may lead in cases where a crime or threat to public safety is involved (e.g. deliberate release of a toxic chemical). For large accidental fires, the response may be led by the fire and rescue services. In the event of an incident with significant health and environmental impact, a Strategic Co-ordinating Group can request the establishment of a Science and Technical Advice Cell (STAC) to coordinate the scientific and technical advice, including health advice during the response to an emergency.

Case study: levels of national emergency response in the United Kingdom

At national level, the UK government defines three levels of response: significant (level 1), (e.g. severe weather), serious

(level 2) (e.g. pandemic influenza), and catastrophic (level 3). Level 1 emergencies require the involvement of a lead government department or a Devolved Administration. Level 2 and level 3 emergencies require a response coordinated by the Cabinet Office Briefing Rooms (COBR). The 7 July London bombings provide an example of a level 2 emergency. The Prime Minister would lead a level 3 emergency with very high and widespread impact (e.g. Chernobyl-type accident).

Once activated, COBR coordinates and monitors the national response, supported by a number of cells providing authoritative advice on, for example, intelligence, recovery, impact management, response, and public information. Specialist scientific and technical advice will be coordinated by the Science Advisory Group for Emergencies (SAGE). The SAGE membership will depend on the type of incident but will include national specialist advisors and, if necessary, the wider scientific and technical community. For example, a major release from an industrial site in England would involve the site operator for site-specific information; the Department of Health and Public Health England for scientific and technical advice on the health effects of the release; the health service to coordinate the NHS response; the health and safety, environmental, and food regulators to provide advice on relevant areas; and the national meteorological agency to provide weather information, for example, dispersion modelling of the release.

Situation reports (Sit Reps) will be required from government departments, agencies, and regional and local responders to build an up-to-date and accurate picture of the incident, its impacts, and what is being done to manage them. The output will be the 'Common Recognised Information Picture' or CRIP shared with all responders.

Fig. 11.11.2 shows the link between local, regional, and national interactions in the UK emergency response depending on the geographical spread and severity of the impacts.

Exposure and risk assessment

Problem formulation

Immediate risks to health should be addressed by precautionary advice given at an early stage. This will usually be in line with pre-prepared advice contained in the emergency plans (e.g. sheltering or evacuation to reduce or eliminate exposures, depending on the scenario).

A clear description of the problem assists in selecting the level or type of risk assessment required (e.g. qualitative/quantitative) and ensuring that risk management decisions are as robust as possible. Basic information is required at an early stage such as:

- ◆ What time did the incident occur (and how long is it likely to last)?
- ◆ What is the location of the incident?
- ◆ What is the hazard, that is, the chemical or radiological agent that may cause adverse health effects?
- ◆ Who is potentially affected?

Communication with partner agencies is a vital aspect of the emergency response which will allow rapid access to the good quality scientific and technical information needed for effective public health risk assessment and response. Additional information gathered through these channels will fill in the information gaps and refine the risk assessment. It is important to record and update all the information received, noting the uncertainties and assumptions.

A very basic conceptual model can be used at this stage. For emergencies, this is presented in the form of the 'source–pathway–receptor' model (Box 11.11.1). Without a source–pathway–receptor linkage, harm will not occur.

Risk assessment

Risk assessment is one component of the risk management process. The risk assessment stage will take into account the probability of an event occurring and the magnitude of the consequences of the event. In the early stages of an incident, the risk assessment will be subjective but will be refined and quantified as more information is gathered.

The generic risk assessment process involves four stages: hazard identification, assessing the consequences, assessing their probabilities, and characterizing the risks and uncertainties (Gormley et al. 2011). In an emergency situation, the public health risk assessment can be done through a combination of qualitative and quantitative methods.

The source

Information about the source can be obtained from the site operator for industrial accidents. In the United Kingdom, if the incident is the result of a road traffic accident involving radioactive

materials, information is available from RADSAFE whose remit is to provide advice and assistance to its members. The specialized fire and rescue's hazardous materials and environmental protection officers will provide invaluable, on-the-scene information in the early phase of a chemical incident. The key requirement is to identify the chemical(s) released and its/their physical form. The chemical's physico-chemical properties will provide information on its ease of spread throughout the environment. Understanding its toxicological properties and the quantities released is also key to successful risk assessment.

Most incidents involving chemicals and radiation will require access to specialist advice to interpret the information gathered. It is important to remember that the substances contained in a product inventory are not always those of most public health concern. For example, a fire may break chemicals down to form complex molecules and other hazards depending on the temperature and oxygen availability.

The pathway

The pathway describes how the pollutant spreads in the environment. If it is a gas, the main pathway will be through the air and dispersion modelling can be used to predict how it will move spatially and temporally. Liquids, depending on their volatility, may disperse through the soil, water, and air. Solids will disperse more slowly; however, fine solids will form dusts that can disperse quickly in the right conditions. Food can also be part of a complex exposure pathway, for example, some chemicals travelling in the air can be deposited on crops which are later ingested leading to exposure.

Exposure to a substance can be assessed through a combination of methods: by sampling or monitoring the external environment, by modelling the external environment, or by measuring the substance in the body.

Timely information on the type, concentration, and environmental distribution of the pollutants is needed for public health risk assessment. The concentration of a substance in the environment can be monitored and/or modelled with varying degrees of accuracy and precision depending on the time and resources available. Unless arrangements have been made at the planning stage for rapid deployment of sampling and measurement equipment, information may be received too late to inform the risk assessment.

An example of a planned monitoring system is the UK Radioactive Incident Monitoring Network (RIMNET), set up in 1988 to monitor the consequences for the United Kingdom of nuclear incidents abroad. RIMNET comprises 96 monitoring stations around the United Kingdom. A range of organizations can submit monitoring data to RIMNET. Public Health England advises government departments on the public health interpretation of radiation monitoring data.

Environmental matrices containing the substance of interest (e.g. air, food, water, dust, or soils) can be used to aid public health risk assessment. In certain circumstances, real-time measurements can be made, for example, for chemicals in air or monitoring of levels of radiation. Monitoring should be planned as soon as possible. The monitoring strategy should ensure that the samples taken are representative of the general bulk material as substances are rarely homogeneously dispersed in the environmental media. The methods used to take and store the samples should

Box 11.11.1 Example of source–pathway–receptor model

Source: chemical release due to road traffic accident involving a tanker.

Pathway: dispersion of the chemical through the air.

Receptor: residents (children and adults).

not degrade the substance of interest. The analytical techniques used must be appropriately sensitive, accurate, and reproducible. For direct measurements, monitoring over the right time interval allows comparison with any predefined health based standards.

Modelling external exposure involves computer simulation to estimate the pollutants' concentration and predict their behaviour through one or more environmental media. Air dispersion models are often used during large-scale incidents. A number of data sources are required, depending on the sophistication of the model, for example, source term, weather data, and topography.

Monitoring and modelling should be considered together in a multi-agency group attended by specialist scientific staff as information gained from monitoring could be used to inform the model and model outputs can predict areas to monitor for effective exposure assessments. The uncertainties for this type of external exposure assessment include the accuracy, completeness, and relevance of the data.

The receptors

For the purpose of a health risk assessment, the receptors are the people potentially exposed. Some population groups exhibit adverse health effects when exposed to lower pollutant levels or react more quickly than the general population. These are called 'sensitive receptors'. Children, the elderly, people with pre-existing diseases, and pregnant women may be sensitive receptors, depending on the hazard involved.

The primary exposure routes for chemicals are absorption (contact between the chemical and the skin or eyes), inhalation (breathed into the lungs), ingestion (through contaminated food and/or water), and injection (through breaks in the skin). For radioactive materials, an additional exposure route is external irradiation, where gamma and/or beta radiation particles emitted by materials outside the body penetrate the skin and deposit their energy inside. Alpha particles are a risk to human health only when taken into the body by inhalation, ingestion, or through open wounds as they are easily stopped by the dead layers of the skin.

The duration of exposure is important to assess and estimate health risks. Single or short-term exposures to some chemicals at a sufficient concentration can trigger adverse health effects (e.g. carbon monoxide). Other chemicals require exposure for days and months to cause lasting health effects (e.g. some respiratory irritants).

Once inside the body, chemicals move through the metabolic pathways, are transformed, and either stored or eliminated. Biological markers of exposure can be used to enhance the risk assessment and measure the internal dose. However, the right study design, including the choice of the most appropriate body fluid or tissue to be tested, collection, storage, processing, and analytical protocols require a thorough understanding of the exposure route, absorption, and metabolism of the chemical of interest. Specialist scientific advice should be sought before considering human bio-monitoring to assess exposure.

Risk characterization

This step of the risk assessment is usually a quantitative assessment involving a comparison of the concentrations measured against health-based values, where they exist. These values are different for different chemicals and for the same chemicals in different environmental matrices. For example, health guidelines have been set for lead in air, water, and in blood. Health-based values

are derived at levels below which adverse health effects are considered unlikely for so-called threshold chemicals. Exposure to some chemicals can lead to health effects at any level of exposure, these chemicals are called 'non-threshold chemicals' and health-based concentrations are set for tolerable risks.

For some airborne chemicals, the use of Acute Exposure Guideline Levels (AEGLs) can be useful. Three values are identified, the level of the chemical in air at or above which the general population could experience notable discomfort (AEGL1), the level of the chemical in air at or above which there may be irreversible or other serious long-lasting effects or impaired ability to escape (AEGL2), and the level of the chemical in air at or above which the general population could experience life-threatening health effects or death (AEGL3).

Radiation has both threshold and non-threshold effects. Acute injuries occur above a threshold high dose. At lower doses there are stochastic risks, mainly of cancer induction that are assumed to have a linear no-threshold dose-response function. Public and occupational exposures to radiation aim to be as low as reasonably achievable (ALARA) within the context of specific dose limits to aid emergency planning. Strenuous efforts should be made to avoid acute radiation injuries in emergency situations.

Case study: the Goiânia accident

On 13 September 1987, two people entered an abandoned private radiotherapy institute and removed a caesium-137 teletherapy unit in the city of Goiânia, Brazil (International Atomic Energy Agency 1998). They took the source home and dismantled the source assembly. The source capsule ruptured and dispersed some of the radioactive caesium chloride salt it contained. The items were sold for scrap.

Over the next few days, people noticed that the material glowed blue in the dark. Friends and relatives came to see it and took some of the material to show their families; this led to the widespread contamination of people and the environment. Some decorated their skin and ingested the caesium present on their hands. A number of people suffered from gastrointestinal symptoms and skin injuries and sought medical attention. Eleven people were hospitalized but were diagnosed as suffering from food poisoning and other skin diseases.

The scale of the problem was assessed by monitoring and several areas were evacuated. Medical triage was carried out in a local stadium where people were decontaminated. Medical examinations and interviews were carried out. The more seriously exposed persons were found to be suffering from acute local radiation injury to the skin from beta irradiation and to deeper lying tissue damage from penetrating gamma radiation.

Over time, 112,000 persons were monitored, of whom 249 were found to be contaminated either internally or externally. Inhalation was not considered to be a major route of exposure; this was confirmed by ambient air monitoring. After their initial whole-body external exposures, patients who had also been exposed internally suffered subsequent chronic, low-dose, whole-body exposure. Urine and faecal samples were used to screen for internal contamination. More than 4000 urine and faecal samples from a total of 80 persons were analysed in the period from October 1987 to January 1988. Prussian blue was given to patients to treat internal contamination by increasing the excretion of caesium isotopes and thus reducing the dose.

Four people died within 4 weeks of being admitted to hospital.

From an environmental point of view, aerial and foot surveys covered 67 square kilometres of urban areas and over 2000 kilometres of road. The worst contamination was confirmed to be within a 1-square kilometre area including the scrap yards and residences where the source was dismantled and caesium chloride handled. Eighty-five houses were found to have been significantly contaminated; most were decontaminated by vacuum cleaning and high-pressure water jets. Four houses had to be demolished. Countermeasures related to soil and fruit were only necessary, however, for soil and fruit within a 50-metre radius of the main contamination centre. Drinking water contamination was found to be low and groundwater was free of contamination.

This incident generated large quantities of low-level radioactive wastes (3500 cubic metres). This waste is now buried in a near-surface repository on the outskirts of the city, where it must be isolated for the next 300 years.

The United Kingdom introduced the High-Activity Sealed Radioactive Sources and Orphan Sources (HASS) Regulations 2005 to reduce the opportunity for accidents involving radioactive sources such as the one in Goiânia.

Countermeasures and risk management techniques for public health protection

The next stage of the process considers the options available to prevent or control the risks. It is likely that more than one possible risk management strategy will be available.

Countermeasures fall into two categories, preventative countermeasures to avoid or reduce people's exposure (decontamination, sheltering, and evacuation) and those used to treat casualties once exposure has occurred (antidotes and medical treatment). It is important to stress that lifesaving treatment should always take priority. Health plans should include arrangements for ambulance transport of contaminated casualties with serious injuries, without exposing ambulance crews to significant risk.

A combination of countermeasures can be used depending on the type, scale, and severity of the incident. This should be continuously re-evaluated as the incident evolves and more information is collated to inform the risk assessment. For all of this to happen effectively, multi-agency plans need to be developed and exercised so that organizations understand their roles, how they will communicate with each other and members of the public, and the pros and cons of specific countermeasures. The plans should allow responders to scale the response up or down depending on the severity of the release and the outcome of the risk assessment.

For high-risk fixed industrial sites and nuclear installations, plans usually include local sheltering and evacuation strategies based on maps dividing a geographical area into zones, taking into account local infrastructure (e.g. availability of local transport systems, location of rest centres) and effective warning and informing of residents within a certain emergency zone (e.g. using sirens).

For all countermeasures, vulnerable sections of the community need to be identified early as they may require assistance (people with special educational needs/disabilities, requiring medical support, the elderly, the frail, and children) or not be able to understand the messages. Some population groups may be particularly sensitive to the substance released; for example, consideration

should be given to minimize the exposure of pregnant women in a radiation incident.

Case study: Graniteville train crash 2005

On 6 January 2005, at 2.40 a.m., a freight train collided with a parked train, derailling a number of cars in the centre of Graniteville, a small community just outside Aiken in South Carolina (Mitchell et al. 2005).

Approximately 60 tonnes of liquefied chlorine gas was quickly released. Residents called the emergency services within a minute of the crash and reported a bleach smell and smoke on the ground. The fire department issued a shelter in place message at 6.30 a.m. The evacuation message was not issued until 2.30 p.m. Delays in advising evacuation resulted in a large number of sheltering people experiencing adverse health effects.

Approximately 5400 people were evacuated, 554 sought treatment in hospitals, and 75 were admitted. Nine people died.

Lessons identified from this incident were that better emergency response planning for chemical incidents was needed and that emergency plans for local risks needed to be developed and exercised with the local community. Emergencies from fixed sites are often used in emergency planning; however, transport risks need to also be planned for.

Sheltering, shelter in place

Shelter in place (also called shelter *in situ*) is invoked when the safest place to take refuge or cover from an actual or perceived danger is indoors (e.g. in a house, business place, or school). Most buildings can provide significant protection against short-lived chemical and radiation releases. In the United Kingdom, the message used by the emergency services, usually through the local media, is 'go in, stay in, and tune in' and was developed by an independent National Steering Committee on Warning and Informing the Public (HM Government 2004).

Vehicles, boats, and caravans offer a lower level of protection than residential building, so sheltering in these conditions should be a last resort and for short periods. Closing windows, air conditioning, and vents will help reduce airborne exposures.

Evacuation

Evacuation can range from small-scale, locally managed and coordinated evacuation (one or two streets) to mass (or wide-area) evacuations requiring national coordination (e.g. for wide-area flooding) (HM Government 2014). Evacuation should be conducted in a controlled, systematic way to minimize potential exposure and other risks. Mass evacuation is a complex undertaking as transport, support for vulnerable groups, and the availability of shelter in a designated local authority rest centre (e.g. a school or leisure centre) will be necessary. Longer-term psychological impacts of unscheduled evacuations amongst vulnerable populations must not be underestimated.

Evacuation may be preferred for longer-lived incidents, especially when it can be implemented before people are exposed (e.g. before a release reaches a community), or before an incident happens.

The fire and rescue services will activate pre-existing plans for evacuation of members of the public and non-essential personnel to a safe distance for defined scenarios, for example, where there is an explosive risk.

Decontamination

Decontamination usually refers to external decontamination of people to reduce further exposure or avoid secondary contamination. In the United Kingdom, the management of public mass decontamination is the joint responsibility of the fire and rescue services and the Department of Health. The fire and rescue services are equipped with mobile mass decontamination units including disrobe and re-robe packs. Following the terrorist attacks in the United States on 11 September 2001, new equipment and training procedures, particularly focusing on mass decontamination (Health Protection Agency 2009) in public places in the event of a chemical, biological, radiological or nuclear (CBRN) attack, have been provided to the UK fire and rescue services. Ambulance services and hospitals also have access to decontamination pods or facilities.

Contaminated casualties should be evacuated to a safe environment and individual or mass decontamination should be carried out as soon as possible, preferably within 15 minutes of exposure for maximum benefit. Casualties are usually asked to remove their clothes from head to foot to reduce the risk of inhalation of any contaminant. Recent research in decontamination techniques shows that, in the initial phase of an incident involving non-caustic chemicals, the blotting and rubbing of exposed skin surfaces with dry absorbent material, that is, dry decontamination, is most effective unless the use of water is recommended by expert advisors.

The water decontamination method is the rinse-wipe-rinse method. After removal of contaminated clothing, casualties are asked to drench themselves under a lukewarm shower to remove water soluble material and dusts (rinse), apply a detergent solution using a soft brush to remove organic matter (wipe), and drench again to remove the detergent (rinse).

Non-ambulant casualties and those with open wounds should be decontaminated by trained personnel.

People monitoring for radioactive contamination

Non-invasive screening of the public for radioactive contamination can be used to triage large numbers of people and assess the need for medication intervention, decontamination, and/or further contamination monitoring. Depending on the radionuclides, walk-through portals and hand-held equipment can be used to detect internal or external contamination. Portable or transportable whole-body monitors should be used to detect the presence of internal contamination and for dose assessment following decontamination.

Antidotes

Treatment for chemical and radiation exposure is mostly symptomatic and supportive. Very few antidotes for individual toxins exist and where they do, they should be administered under medical supervision.

For nuclear reactor accidents where iodine usually forms a significant part of the release, the administration of stable iodine before or in the few hours after exposure, in conjunction with sheltering can form a very effective countermeasure strategy.

Depending on the chemical, antidotes can be used to form an inert complex with the poison, speed up detoxification, reduce the rate of conversion to a more toxic compound, and so on. For

example, chelating agents such as dicobalt edetate are recommended to treat moderate to severe cyanide poisoning in adults and 2,3 dimercaptosuccinic acid (DMSA) has been recommended for lead poisoning. Prussian blue (ferric hexacyanoferrate) is used to increase the faecal excretion of caesium and thallium from the body, thus reducing the internal dose.

In the United Kingdom, health professionals seek advice from the National Poisons Information Centre (Public Health England 2013).

Recovery

Recovery is the process of restoring and rebuilding the community in the aftermath of an incident; this can take years or decades for the most serious events. Most successful recovery strategies begin during the emergency phase of the incident and begin to address the environmental, health, infrastructure, and economic impact of the incident as soon as possible. Recovery roles and responsibilities should be planned and rehearsed in a multi-agency setting. Local authorities will usually lead the recovery phase of the incident and comprehensive guidance and toolkits have been developed to support evidence-based decision-making (Public Health England 2009, 2012).

Public reassurance in emergencies and incidents

The scientific basis of accurate public risk communication is mature. There is also a considerable literature on the need to build trust in the systems that will be used in an emergency to protect casualties, the public, and emergency responders. More recently, papers considering emergency incident response communication as a contributory factor in public concern have been published (Drury et al. 2012; House of Commons Science and Technology Committee 2012; Pearce et al. 2013a, 2013b).

Radiation and chemical exposures can provoke all of the 'fright factors' that are known to be most feared by the public (Slovic 1987; Meara 2002). There is an extensive literature and a lot of guidance to help risk communicators in emergency situations (Department of Health 1998; Cabinet Office Strategy Unit 2002; Calman 2002; HM Treasury and Government Information and Communication Service 2003; Wessely et al. 2005).

Regulators and organizations with responsibilities for health protection have been criticized for taking a low media profile during emergencies (House of Commons Science and Technology Committee 2012). Scientific organizations can find it difficult to communicate in high-pressure situations where the facts are not known and the uncertainties about what may occur are extensive.

Basic principles of good public communication in incidents include:

- ◆ Decide who are the best organizations and people to deliver the public messages.
- ◆ Begin communicating as soon as possible, acknowledging inevitable uncertainties.
- ◆ Use national helplines that have a large capacity to deliver the essential health protection messages.
- ◆ Take account of people's desire to find out about the safety of their loved ones.

- ◆ Comparing familiar risks with unfamiliar ones can help put risks into context, but care must be taken to ensure that elective risks are not used as the comparison for unavoidable risks. In general, people declare a lower tolerance for unavoidable risks.
- ◆ Always tell the truth or give the reason(s) why the truth cannot be given. There may be unknown factors or facts that cannot be shared for security purposes; if this is the case, explain why and what these are.
- ◆ Develop public generic information materials in 'peacetime' that can be adapted quickly during an incident to speed up delivery of public health advice. These should include information about the mechanisms of harm, locations where harm may occur, the things people can do to protect themselves, and how effective these will be. Accurate information is likely to improve compliance with public health advice.
- ◆ Develop experience in using modern communication methods, such as social media to deliver important health messages.
- ◆ Remember that the emergency responders may need information and support as well as members of the public.
- ◆ One session of psychological debriefing after recent trauma does not reduce psychological distress or prevent the development of post-traumatic stress disorder (Rose et al. 2002).

Case study: public risk communication during the polonium contamination in London 2006

In 2006, following enquiries relating to an unexpected death, radioactive polonium was found to have contaminated many public places in London (Rubin et al. 2007; Morgan et al. 2008). Detailed investigation eventually revealed that the public health risks were low, but this was not known at the start of the incident. The investigation needed clear objectives and a prioritized approach to make best use of the environmental and people-monitoring facilities that were available.

There was potential for significant public concern, disruption, and economic impact, which did not happen. A British Airways press release stimulated a disproportionate response and for a brief period there was radiation screening of passengers coming from the United Kingdom at an airport in the United States.

While the emergency response was still going on, researchers carried out a random telephone survey of 1000 Londoners and more than 100 potentially exposed people who had visited contaminated venues at the relevant times. The random survey showed that the health protection communications, which included significant media interviews and a daily press release, were generally successful as only 11.7 per cent of those who replied perceived their health to be at risk because of the incident. The number of visitors to London did not decrease.

The daily health protection press releases were considered important to keep people informed. Seventy-one per cent of responders understood that they could not be contaminated if they had not been in the relevant venues. Fifty-eight per cent of responders understood that polonium is only dangerous if it enters the body.

The authors suggested that the factors contributing to this effective public communication were:

- ◆ The incident was linked to espionage rather than terrorism in the public consciousness. People who thought the motive was

terrorism (15 per cent of the sample) were significantly more likely to feel that their health was at risk than the people who attributed the incident to espionage, criminal activity, or spying.

- ◆ The public perception was that one person had been targeted. People who thought the incident was intended to harm the general public (14 per cent of the sample) were significantly more likely to feel that their health was at risk than those who thought that it was intended to harm one person only.
- ◆ The people who had been in the contaminated venues were significantly less deprived than average. Lower earners were more than four times more likely to feel that their personal health was at risk.
- ◆ It was not possible to investigate the impact of the low-key way in which venue monitoring was conducted (i.e. without the use of sophisticated personal protective equipment). However, the appearance of 'suited and booted' staff in public places where the mass media were present could have caused alarm.

Despite these positive outcomes, people who had been in contaminated areas and had been offered urine testing tended not to be happy with the information they received. Some of this displeasure was inevitable because they wanted details related to the criminal investigation that could not be made public. Other people wanted more numerical information about their test results. Uniquely for polonium in urine testing, this was difficult to provide because the same amount of urinary excretion can be associated with a radiation dose that varies by a factor of ten, depending on the assumptions made. For the lowest category of risk, there were insufficient resources to undertake detailed dose assessments, using individual-specific assumptions so people were only told that their results were 'of no concern'. These complexities are not easy to put across in the midst of an emergency incident.

A small number of people (seven out of 3837) who contacted the telephone helpline that was set up for the incident failed to be reassured by direct discussion with specialist health protection staff, even if they had not been at any of the contaminated venues (Morgan et al. 2008). Of these, four were contacted by a psychiatrist who found evidence of pre-existing psychological stressors and a history of health-related anxiety. The authors concluded that access to psychiatric help may be useful in incidents such as the polonium contamination in London.

Follow-up of affected populations

There are two main reasons to undertake follow-up of populations affected by chemical, radiological, or environmental incidents: part of the long-term response to help and provide services for affected people, and to gather scientific information about the health effects of the exposures that they may have received. In most cases, the decision to set up a follow-up study is done for elements of both reasons.

The former may be particularly useful if there is to be ongoing treatment of or compensation for affected people. Compensation usually takes many years to organize, by which time the affected people may have moved away from the local area or died.

Follow-up of affected cohorts provides a unique way to study the health effects of toxins on the general population and much useful information can be gained. One of the key recommendations of a UK government Committee on Toxicity inquiry into the

Lowermoor aluminium water pollution incident was that ‘it is vital to identify populations which may need to be monitored in any later epidemiology studies as early as possible after the incident. If identification of these populations is delayed, exposed individuals may move out of the area and be lost to follow up’ (Committee on Toxicology of Chemicals in Food, Consumer Products and the Environment 2013).

There are two major problems with emergency response follow-up studies that distinguish them from other epidemiological research. Firstly, the decision to set up the study may need to be taken very early on in the incident, in order to capture, as fully as possible, the cohort of participants for the study. Secondly, it may be more difficult than in a planned study to determine each individual’s exposure to the noxious agent.

It is not straightforward to decide if a follow-up study is needed in each incident. Done properly, the work will be resource intensive in all but the smallest of incidents. If the cohort does not accurately reflect all those who may have been harmed, then its scientific power and usefulness as a tool to help patient care may be limited in the long term. Paranthaman et al. (2012) have proposed a decision framework to help responders decide if a follow-up health register study is indicated based on a Delphi consensus study of emergency responders and epidemiologists (Box 11.11.2). The study presented participants with four scenarios and asked responders whether a follow-up study should be set up and why. Although there was a spectrum of views from the range of responders, 11 factors were defined by the participants as important in making the decision about setting up a health register. The factors are not mutually exclusive and their relevance needs to be debated by the team setting up the follow-up study.

Measuring individual or group ‘doses’ to noxious agents may be difficult in emergency situations as resources are rightly focused on more urgent aspects of the response. For some agents, for example, intakes of radionuclides, there are accurate biodosimetry methods that can be used in the weeks and months following an incident to retrospectively assess exposure. However, for other agents there is no measurable signal after the event, or the signal decays very quickly. This poses real logistical problems if large numbers of people need to be measured and may well swamp national capability to perform such measurements. Triage arrangements may be needed to ensure that people with the highest clinical need for testing have priority.

In other situations, environmental measurements, combined with information about where people were at the time of the incident, what they were doing, and what injuries they may have suffered allow post hoc assessment of likely ‘doses’. These can be calibrated by actual measurements taken in smaller numbers of people with similar locations and behaviours at the time of the release.

Some of the work to set up a follow-up study is needed in the acute phase of the incident. Therefore emergency plans need to specify how the decision to set up a follow-up study will be taken and plan for the resource and practical implications of this work. Exercising these plans will help to spot rate-limiting steps and identify actions that can be done in advance, for example, detailed understanding of how to collect patient data from hospitals, community services, and rest centres, developing generic data collection, and patient information forms that can be adapted when an incident occurs.

There are ethical and data protection concerns whenever new follow-up studies are started. The objectives of follow-up studies

Box 11.11.2 Important factors to consider when setting up a health register after a major incident

- ◆ There is exposure to an agent with potential to harm public health but there is little prior experience, or exposure to a well-known agent but the incident has novel characteristics.
- ◆ There is insufficient knowledge of the type and latency of health effects, but reasonable grounds to suspect that they will occur.
- ◆ The incident is likely to lead to significant political/public/media interest that may increase societal concern.
- ◆ The register will be used in the clinical management of affected patients, especially in the long term.
- ◆ There is a reasonable possibility of short- or long-term physical and/or psychological sequelae from the incident.
- ◆ There is potential for specific adverse effects in vulnerable groups, for example, pregnant women, potential for teratogenicity.
- ◆ Follow-up studies have the potential to produce significant new knowledge about health effects of exposures and benefit the wider population as well as affected individuals.
- ◆ Follow-up studies have the potential to enable interventions to reduce the impact of exposures.
- ◆ It will be possible to identify the population at risk including detailed demographic data (though not necessarily collected at the time of the incident).
- ◆ It will be possible to identify, measure, or estimate exposures of individuals or groups (though not necessarily at the time of the incident).
- ◆ There are sufficient data on the spatial distribution of the contamination or exposure (though not necessarily measured at the time of the incident).

Adapted from Paranthaman, K. et al., Development of a decision framework for establishing a health register following a major incident, *Prehospital Disaster Medicine*, Volume 27, Issue 6, pp. 524–30, Copyright © World Association for Disaster and Emergency Medicine 2012, reproduced by permission of Cambridge University Press.

must be clear at the start and data protection and other ethical aspects considered at the emergency planning stage. This will minimize workload and delay when setting up the most complete possible register of affected individuals in an emergency situation. It is not ethical to collect and store information 'just in case' without explicit consideration of how these data can help the individuals concerned or contribute to an adequately powered scientific study.

A pragmatic approach at the early stages of any incident, before the decision about a follow-up study has been taken, is to ensure that basic contact details are logged by all members of the public interacting with emergency responders. If a follow-up study is advised, these people can be contacted again for more information and advice.

Patient questionnaire and other data collection techniques need to be developed with care to ensure that all the relevant information is obtained in the most efficient manner. Detailed, timed information about where the person was, what they were doing, and other aspects of 'exposure' is usually needed as well as information about symptoms and health status, including mental health status. The objectives of the study should be at the heart of the data collected by that study.

Identify and publish the lessons learned

Reporting incidents is vital to share learning, decrease the chance of the incident reoccurring, and to improve emergency response. However, many incidents and emergencies are very poorly documented. Incident reports may also be useful for members of the public who have been placed at risk, colleagues who are responding to similar incidents, and public health professionals who are called to give evidence in public or legislative inquiries into the incident. Only with detailed documentation can lessons be identified that can then change policy and practice.

A process to ensure consensus on what information will be gathered and how data collection will be organized during and after an incident or emergency should have been established as part of the pre-incident emergency planning. Collation of data for reporting should start as soon as possible during the crisis event with plans for continuous updating as more data become available from the multidisciplinary (or potentially international) response.

Organizations, including public health partners, performing incident or emergency responses should jointly develop and document how the quality and validity of information are assured. This needs documented procedures and training for incident responders, including administrative staff, in the methods for information gathering, analysis, and quality assurance.

Kulling et al. (2011) set out a summary of the requirements for reports on health crises and critical health events and recommended issues that should be managed actively at an early stage in a response. These include:

- ◆ The mandate for the emergency report and that of the respective authority/organization.
- ◆ Early identification of the authors and their responsibilities.
- ◆ Ethical approval and quality assurance statements for the report if required.
- ◆ A summary of the pre-event status if needed, such as baseline disease patterns and user patterns of hospitals and health

facilities as well as other relevant previous incidents or disasters described as well as preparedness plans.

- ◆ A summary of the incident or emergency.
- ◆ A method statement to include descriptions of hazard and exposure assessments, decision flow, and information management.
- ◆ A description of the interventions and how they were evaluated in terms of effects, outcomes, and impacts balanced against the goal(s) and objectives of the interventions. It may be useful to distinguish between immediate-, medium- and long-term impacts.
- ◆ Coordination and collaboration between organizations from health and other sectors.
- ◆ Adverse health effects in the responders.
- ◆ Identify interventions that restore normality to the pre-event level, including how responding organizations intervened to provide resilience and reduce vulnerability in people at risk.
- ◆ Consider summarizing the lessons identified by describing:
 - ◆ What went well.
 - ◆ What went badly.
 - ◆ What could be done better.

The final task is to publish the report in an appropriate peer-review publication for all to share and learn from.

Conclusion

This chapter has explained the stages of response to radiation, chemical, and environmental emergencies using a generic 'all hazards' framework and a 'source-pathway-receptor' risk assessment model which is adaptable to any situation and conforms with international obligations.

In recent years there have been many chemical, radiation, and environmental disasters that have challenged the emergency preparedness of countries around the globe. Adequate resources for response and pre-planning are vital to deliver a slick, professional, and proportionate response and to define the important factors to consider when setting up a health register after a major incident. The knowledge gained by careful evaluation of emergency responses can greatly improve the efficiency of emergency preparedness (Lurie et al. 2013). However, there are great challenges in doing research under such circumstances. There remain a significant number of evidence gaps and so detailed documentation and follow-up of future incidents will continue to be needed to fill those gaps and improve emergency preparedness and response in the future.

Private support of public health

Quarraisha Abdool Karim and Roger Detels

Introduction to private support of public health

Private support for public good may be understood as the cooperation between private individuals and/or the commercial sector and the public sector in order to more effectively meet the needs of society locally or globally (Buse and Waxman 2001). This relationship is not necessarily unidirectional, and in several instances, also benefits the giver through increase in turnover from positive product or company branding through media coverage that accompanies giving (Broadbent and Laughlin 2003). The World Health Organization (WHO) defines public–private partnerships (PPPs) in the health sector as the bringing together of a set of actors for the common goal of improving the health of populations based on mutually agreed roles and principles (Kickbusch and Quick 1998). While these principles are based on the founding ideas and values of human ethics such as beneficence, non-maleficence, autonomy, and equity (Buse and Walt 2000a) the reality is that the relationship between giver and recipient is not an equal one.

Over time, while anonymous individual giving has continued, some of these ad hoc institutional contributions have evolved into more defined and legally recognized structures also referred to as philanthropic organizations and includes giving by more wealthy individuals and families as well as corporate institutions. Giving, particularly by North Americans, dates back to the formation of ‘foundations’ in the earliest years of the twentieth century as a result of wealth acquired through industrialization. In the United States, this idea was catalysed by a ‘tax break’ provided by the US government to private companies and citizens who donated a certain proportion of their wealth to federal or state government projects or priority initiatives (Butler 2001). Private entities had autonomy to choose which government or global projects or priorities they would support, and the extent thereof, while deriving the benefit of reduced taxation.

This type of charitable tax deduction by the US government, has allowed foundations to reduce their tax burden by as much as 25 per cent (Strom 2007). *The New York Times* has estimated that charitable deductions cost the US government US\$40 billion in lost tax revenue in 2006 (Strom 2007). In effect, this substantial private philanthropic support means that the foundations, and not the US government, are determining where significant public funds are spent. Philanthropists and foundations take pride in their autonomy in determining what to invest in and traditionally

have identified areas that minimize overlap and define their giving identity. Eli Broad, one of the major donors, summarizes the essence and impetus for private giving by asserting that smart philanthropists get more for their money than governments because they know how to invest wisely (Strom 2007).

However, it is important to recognize that foundations often determine their targets and objectives on personally identified and defined priorities rather than an objective assessment of international and national need. Foundations are likely to invest in areas that governments may be reluctant to for political or moral reasons, for example, sexuality education, gender-based violence, fertility control, and harm reduction programmes.

History of giving

One of the earliest known foundations in the United States was the Russell Sage Foundation that was founded in 1906 with a focus on working women and poverty-related illnesses (Hammack and Wheeler 1994). The establishment of larger and more encompassing foundations began with the founding of the Carnegie Foundation by Andrew Carnegie in 1911 ‘to do real and permanent good in this world’ (Carnegie Corporation of New York n.d.) followed by The Rockefeller Foundation in 1913 (Menasha and Hsig 1915).

These early gifts had a significant impact on institution creation to support and build public health capacity. Public health provided the optimal mechanism through which Rockefeller philanthropy was able to apply their scientific findings for the public good (Birn and Fee 2013). The Rockefeller Foundation established the International Health Commission in its first year (The Rockefeller Foundation 2013). This was the first allocation of funds from private sources for international public health activities and had a wide sphere of influence—52 countries on six continents and 29 islands to improve their public health systems. The Rockefeller Foundation simultaneously initiated a 20-year programme to support the Bureau of Social Hygiene which focused on research and education on fertility control, maternal health, and sex education. This foundation played a key role in founding the world’s first schools of public health, first at Johns Hopkins, then at Harvard, and later in other parts of the United States, as well as in 21 other countries that includes the establishment of the London School of Tropical Medicine and Hygiene in 1921, the China Medical Board in 1914, and the Peking Union Medical College in 1921. The last

two institutions have played a pivotal role in the development of public health in China (The Rockefeller Foundation 2013b).

The Wellcome Trust which was established in 1936 in the United Kingdom is dedicated to supporting research to improve human and animal health. It is the largest non-governmental research funder in the UK and among the largest such providers in the world (Wellcome Trust n.d.).

A hallmark of this type of giving was the insightfulness of individuals in anticipating, prioritizing, and filling an important gap and creating a strong foundation for others, including governments, to build on. This type of nimble, risk-taking investment is in keeping with the business model based on entrepreneurship that sees and seizes opportunities. These are the principles on which the foundation wealth was created—unfettered by ponderous, risk-averse decision-making, never-ending procedures and systems that are the hallmark of most government or public sector bureaucracies.

Current giving

Since those early years of giving, private support for public health has increased in magnitude and scale, particularly in the past decade. Today, the Bill & Melinda Gates Foundation is the largest private grant-making foundation in the world (McCoy et al. 2009) supporting three major programmes worldwide that include a US-based programme to enhance secondary and post-secondary education, a global development programme which focuses on the alleviation of hunger and poverty, and a global health programme that includes increasing access to childhood immunization programmes and research in neglected diseases such as tuberculosis (TB), malaria, and HIV (McCoy et al. 2009). In 2007, 61 per cent of their US\$2.01 billion budget was allocated to health (McCoy et al. 2009). This foundation has single-handedly redefined the concept of individual social responsibility and has inspired similar giving trends across the globe including among wealthy individuals in developing countries. In South Africa, for example, the Motsepe Foundation established in 2013 by Patrice Motsepe, one of the country's wealthiest individuals and listed on the Fortune 500's top ten wealthiest people, has committed 50 per cent of his family wealth to philanthropy and \$US10 million over the next 5 years towards several health, education, and job creation efforts (Morvaridi 2012).

Globally, there are now over 40 major foundations, as well as countless smaller ones (Foundation Center 2014). This increase can be attributed in part to at least three phenomena: substantial growth in personal wealth among a few, global solidarity around the AIDS epidemic and other health threats, and the rise in citizen pressure for corporate accountability/social responsibility. Corporate social responsibility programmes are a new form of giving that adopt a more entrepreneurial approach for product branding, creating brand loyalty and increasing product sales and are not the focus of this chapter.

Globalization of health threats, global solidarity, and the emergence of public–private partnerships

The global burden of disease, especially infectious diseases, disproportionately affects populations in developing countries due to

poverty, weak healthcare delivery systems, inadequate investment in health, and inadequate access to pharmaceuticals, vaccines, and drugs (Widdus 2001). Post-industrial revolution eradication of these diseases in developed countries and the growth of a for-profit pharmaceutical industry have resulted in neglect of research and development in drugs and other medical products for 'diseases of poverty', since such products are perceived as being not likely to generate significant return on their investment.

The rise of multi- and extremely drug-resistant strains of TB (MDR- and XDR-TB), outbreaks of severe acute respiratory syndrome, swine flu, and avian flu, and growing antibiotic resistance have served as sharp reminders of the continuing threat posed by these neglected tropical diseases as well as emerging and re-emerging infectious diseases to everyone regardless of geographical location, in our increasingly globalized world.

Interventions that reduce cost, provide market incentives, and create infrastructure that will allow for product access (Widdus 2001) require the private sector such as pharmaceutical companies to collaborate and work with public and not-for-profit entities to ensure a fast and efficient response (Widdus 2001, 2005). The proliferation of global PPPs (Croft 2005) reflects this approach and is rapidly reconfiguring the global public health landscape (Buse and Walt 2000a).

The substantial investments made by the Doris Duke Medical Research Institute and the Howard Hughes Medical Institute in creating state-of-the-art research facilities and laboratories in KwaZulu-Natal at the epicentre of the HIV epidemic and MDR- and XDR-TB are examples of contemporary US philanthropy in resource-constrained settings to address health challenges that are of local and global importance.

Other examples of private support

Private support of public health, given by foundations, industry, pharmaceutical companies, and professional organizations, has been directed towards disease control and treatment, poverty alleviation, education, training of health workers, infrastructure development, research, improved agricultural practices, health information dissemination, and sponsorship of the many global health alliances.

Specific examples include the provision of drugs and the reduction of drug prices for developing countries, the earliest example being the Mectizan Donation Program by Merck & Co. Inc. for treatment for onchocerciasis (river blindness) in West Africa in 1988. In 1998, GlaxoSmithKline provided albendazole for treatment of lymphatic filariasis as part of the mectizan programme. To date, this ongoing programme has reached more than 80 million people (Mectizan Donation Program 2012).

Another major contribution has been the establishment of special training programmes and scholarships/fellowships for training health personnel. Many foundations are set up for this purpose alone or as part of a broader portfolio. For example, the Robert Wood Johnson Foundation has a clinical scholars programme for US students (Robert Wood Johnson Foundation 2012). Additionally, foundations may provide gifts to schools, which may include equipment or teaching resources.

Another important contribution of private agencies has been to research. The Howard Hughes Medical Institute, for example, was established by Hughes Aviation to conduct research into human

illness (Howard Hughes Medical Institute n.d.) and has established and funded research centres (Howard Hughes Research Institutions) within major academic medical centres in the United States. The Gates Foundation currently supports a large number of research projects targeting a broad range of global health problems. The Wellcome Trust funds a broad portfolio of research in health which includes a long-standing commitment to supporting tropical medicine and public health research. There are also the very significant contributions made by pharmaceutical companies to the research and development of vaccines and treatments, both independently and in PPPs. Increasingly, these efforts are focusing on the so-called neglected diseases that disproportionately affect the world's poorest nations.

HIV/AIDS and tuberculosis: catalysing a new category of giving

The role of activism in advancing the scientific agenda and public access to product advances is most apparent in HIV/AIDS. Since the first reported cases of AIDS in the early 1980s in the United States and the discovery of the causative organism, HIV has spread rapidly across the globe resulting in several million deaths prior to the discovery of effective antiretroviral therapy (Curran and Jaffe 2011; Sharp and Hahn 2011). The transformation of AIDS from a uniformly lethal disease to a chronic, manageable condition has resulted in rapid and phenomenal declines in mortality rates in industrialized countries. This outcome, however, has as yet remained elusive in developing countries that bear a disproportionate burden of the disease.

The hosting of the XIIIth International AIDS Conference in Durban, South Africa in 2000 was the first time that many in industrialized countries came face to face with the plight of the millions of people infected with HIV in developing countries, who were continuing to die because they were unable to access antiretroviral treatment, with high costs posing a major barrier. While the inequities and disparities in terms of access to life-saving drugs and healthcare between industrialized and developing countries were not new, this conference was a sharp reminder and catalysed a whole new approach to public giving in healthcare provision and novel partnerships.

The creation of the Global Fund for AIDS, Tuberculosis and Malaria (GFATM) in 2007 was the quintessential PPP in modern history with respect to harmonizing of resources from multiple sources to address three diseases that in combination are the major contributors to high rates of morbidity and mortality in resource-constrained settings and which contribute disproportionately to the global burden of disease (Vitoria et al. 2009). Funding from the Bill & Melinda Gates Foundation, which by 2012 had provided over US\$26 billion in grants (equal to the total budget of the WHO), stimulated additional large donations by Warren Buffett and the William Clinton Foundation.

The GFATM model builds on the emergence of formalized PPPs to address specific public health challenges, including product development catalysed by The Rockefeller Foundation in the late 1990s with their investment in HIV vaccine development through support for the International AIDS Vaccine Initiative (IAVI) at a time when most had given up on a vaccine. The funds from the Rockefeller Foundation were used by IAVI to leverage funds from other foundations and governments and changed the HIV vaccine

development landscape initially through advocacy efforts and subsequently through investments in product development and clinical trial infrastructure. IAVI energized the quest for a HIV vaccine through its intra-mural programme, expansion of the number of academic institutions engaged in this quest, and even encouraged some pharmaceutical companies to invest in vaccine development.

This model was used subsequently by The Rockefeller Foundation to leverage and harmonize resources to increase access to drugs to reduce mother-to-child transmission (MTCT) of HIV through the MTCT+ initiative coordinated by the Elizabeth Glaser Foundation, and access to antiretroviral treatment for AIDS patients in resource-constrained settings (Barr 2007). The disease- and/or product-specific PPP approach builds on the Bayh-Dole Act that was passed by the US Congress in 1980 (Barr 2007) to promote collaboration in the United States between the federal government, universities, and private pharmaceutical companies in the development and marketing of new pharmaceutical products.

Public-private partnerships

PPPs may be classified or described according to purpose, organizational structure, scope of activity, or approach. Three categories are described as follows (Buse and Walt 2000b):

- ◆ Product-based partnerships that enable access: this includes drug or product donation programmes; bulk purchase of products for low-income countries, for example, the albendazole donation programme; and childhood immunization programme vaccine purchases.
- ◆ Product-development partnerships that enable and incentivize partnerships for discovery and/or commercialization, for example, the Malaria Vaccine Initiative (MVI) established in 1999, the International AIDS Vaccine Initiative described earlier, the International Partnership for Microbicides, and the Tuberculosis Vaccine Initiative.
- ◆ Systems-based partnerships that support government efforts to strengthen health service delivery through health systems strengthening.

A PPP could involve financing from various sources such as equity contributions, debt contributions, bank guarantees/letter of credit/performance guarantees, bond/capital markets financing, mezzanine/subordinated contributions, and inter-creditor agreements in some combination of equity and debt (World Bank Group 2011). Sources may include governments, private foundations, individuals, and the business/corporate sector (McCoy et al. 2009). Some of the wealthiest non-profit charitable foundations globally are the Bill & Melinda Gates Foundation (Vogel 2006), the Stichting INGKA Foundation, the Wellcome Trust, and the Howard Hughes Medical Institute to mention a few. Whilst in previous years giving was largely unregulated, in the light of the post-2009 global financial and economic crisis, a lot has changed. Countries like the United States have called for more strict regulations regarding tax credits for charitable giving by private companies. This would cover federal taxes, but the individual states have their own regulations regarding state-controlled taxes. The increase in the extent of giving to resource-constrained settings by both the US government and private donors has elevated health to diplomatic status wherein good health is viewed as essential for

economic development and social stability at a country level. This goal of ensuring good governance and sustainable societies free of need that is facilitated through bi- and multilateral partnerships between those who have and those who do not through the establishment of a global civil society (Vogel 2006) redefines the meaning of globalization.

Since the inception of PPPs in the United Kingdom (Spackman 2002), almost £56 billion have been attributed to over 800 projects spanning car parks, schools, tolled highways, and power plants (Garvin and Bosso 2008). Globally, a lot of attention has also been given to healthcare, education, social housing (Flinders 2005), and disaster control. Healthcare in particular remains one of the major recipients of PPP funding (Howard 1983, 1991; Novignon et al. 2012). PPP initiatives in health include infectious disease control (Ardian et al. 2007; Kane et al. 2010; Sinanovic and Kumaranayake 2010; Lal et al. 2011; Sturchio and Cohen 2012), drug or vaccine development (Wheeler and Berkley 2001; Nwaka and Ridley 2003; Nwaka 2005; Sanhai et al. 2008), management of hospitals (Goldman et al. 1992; DeVol et al. 2007; Lester 2012), and the building of hospitals (Weiner and Alexander 1998; McKee et al. 2006) or institutes of health.

PPPs can function at a global or country level and imply a mutually beneficial, synergistic alliance between the private and public sectors towards a common goal that is shaped by good governance, equity, and efficiency (Goldman et al. 1992). Whilst benefits of PPPs include the mobilization of funds, technology transfer, strengthened delivery systems (Kraak et al. 2012), greater efficiency in terms of time, scope, and improved options, there are also risks involved. PPPs are not the solution to all health challenges and may not be the most effective or efficient approach in several instances (UK Parliament 2011). For example, the UK Parliament's Treasury Select Committee's review of the PFI scheme in August 2011 concluded that: 'Private Finance Initiative (PFI) funding for new infrastructure, such as schools and hospitals, does not provide taxpayers with good value for money and stricter criteria should be introduced to govern its use'. Careful thought and planning needs to be given to evaluate its appropriateness in each instance to ensure it is not counterproductive.

In the health sector, the most significant PPP exists between the WHO and the corporate sector (Buse and Waxman 2001). This partnership builds on the United Nations (UN) idea of a 'Global Compact' (Williams 2008) that encourages corporate responsibility in the areas of labour, human rights, and the environment in response to globalization (Buse and Waxman 2001). What is distinctive in the case of the WHO is its commitment to health and the principles inculcated in its mission and accountability to its constituency, namely its member states (Buse and Waxman 2001). The corporate partnership with WHO has been met with mixed reactions. Some board members have expressed concerns that commercial interests would mean compromising the integrity of the WHO in terms of subordination of its values, re-orientation of its mission, weakened capacity to promote and monitor international regulations, displacement of priorities, and self-censorship (Buse and Waxman 2001). A number of examples cited of this threat of 'institutional capture' include: (1) the guidelines for the management of hypertension which were unduly influenced by a pharmaceutical

company that had stood to benefit from the drugs prescribed, and (2) deliberations on breastfeeding which were considered to have been censored in favour of the WHO's new set of commercial constituencies (Buse and Waxman 2001).

At a country level, delays in procurement processes or changing needs of communities (Fussel and Beresford 2009) can reduce the efficiency and nimbleness of private partners (Hodge 2004; Fussel and Beresford 2009) or rigid commitments could undermine existing government policies and infrastructure resulting in coexisting government projects being jeopardized and the worsening of the very many issues facing human society in the developing world.

There were more than 90 international partnerships in health in 2004 (Nishtar 2004). The majority addressed infectious diseases, notably AIDS, TB, and malaria. Some involved individual governments, non-governmental organizations, or both forming an alliance with the for-profit sector. For example, Sanofi-Aventis has an extensive international programme of humanitarian sponsorship, including a partnership with the Nelson Mandela Foundation and the South African Department of Health to provide free TB treatment in severely affected areas within South Africa (Sanofi-Aventis 2007).

Other notable partnerships are the global health alliances, such as the Global Alliance for Vaccines and Immunizations, Roll Back Malaria, the Stop TB Partnership, and the Global Polio Eradication Program. They may be principally driven by a company, be legally independent, or hosted by a civil society organization (Nishtar 2004). The Stop TB Partnership, for example, comprises a network of more than 500 partners, including governments of both developed and developing countries, research and technical health institutes, multilateral organizations, civil society, pharmaceutical companies and other industry partners, and is housed within the WHO (Stop TB Partnership n.d.).

Prioritization of need: competing candidates

One of the major issues facing PPPs is the correct distribution of funds based on the degree of need. Depending on the period in question as well as the global climate in terms of crisis management, funds are generally distributed according to urgency and magnitude of need. In the healthcare sector, a lot of attention has been given to the global HIV/AIDS pandemic but recent literature cites a need for a more balanced and better-rounded approach (Bygbjerg 2012). Furthermore, over and above the current agenda of infectious disease particularly in the low- and middle-income countries, there are issues of development, industrialization, urbanization, investment, and ageing, which in turn drive the rising prevalence of non-communicable diseases (NCDs), the majority of which now occur in developing countries (Bygbjerg 2012). Malnutrition and infection in early life tend to increase the incidence of NCDs in later life (Bygbjerg 2012). In addition, the presence of infectious diseases and NCDs together (Boutayeb 2006) can result in adverse interactions (Bygbjerg 2012). Therefore, attempts to fund each health initiative separately are likely to exacerbate the overall situation and distort the countries' health priorities (Bygbjerg 2012). Rather, joint approaches that target improving the healthcare system as a whole are preferable (Bygbjerg 2012).

Challenges

Whilst the concept of PPPs might be conceptually appealing, they are associated with many challenges (Hodge and Greve 2005; Asante and Zwi 2007) such as sustainability; collaboration between donors, governments, health departments and civil society; corruption; and numerous ethical and moral dilemmas. Other challenges which exist include balancing private commercial interests with public health interests, managing conflicts of interest, assessing partnership compatibility, and evaluating partnership outcomes (Kraak et al. 2012). In addition, money borrowed from the private sector is often more expensive than money borrowed by governments and these costs are passed along to the public although the private sector would assert that they can save money in the end because they can operate with greater efficiency. Others argue that the initial capital outlay required may counter the efficiencies gained. Moreover, these expenditures need to be translated into the correct and most effective set of approaches, strategies, and investments for improving the health of the poor (McCoy et al. 2009). There are also issues of transparency and government oversight (Fussell and Beresford 2009). Commercial considerations may limit public oversight during procurement (Fussell and Beresford 2009). Contract provisions may limit changes that are necessary later on in the project in order to safeguard public interests as new public policies which may evolve (Fussell and Beresford 2009).

Private investments and global health—at a crossroads?

Private giving in all its forms, has benefited individuals, institutions in the United States and outside, the recipient countries, and global health enormously and has achieved goals which otherwise would have been impossible to attain and importantly within a relatively short timeline. There is no question that the recent surge in giving has reduced health disparities and changed the global landscape in select diseases and is at an important crossroads. In contrast to private giving in public health in the early twentieth century that was modest, catalytic, and individually determined, the giver today is much more visible, contributions much more substantial, and there is active involvement in shaping the global agenda and in decision-making on priority setting and resource allocation in international bodies and at a country level. The magnitude of the budgets of a few foundations has in some instances overshadowed the work of smaller philanthropic organizations and created uncertainty as to their added value. On the other hand, the skewing by philanthropic giving of the priority setting and investment process globally and nationally, has associated costs that may sometimes outweigh the benefits. For example, some perceive a conflict of interests when a foundation or industry plays a pivotal role at this level of decision-making, particularly where there may be some vested interest in the products used or in determining what proportion of the budget goes to which country. Other concerns include the imposition of unduly onerous conditions on the disbursement and use of the funds. While there is a need for accountability in use of funds for their intended purposes, that accountability should enable the desired outcomes to be reached effectively and efficiently while respecting national sovereignty and avoiding excessive micro-management.

Corporate social responsibility programmes have a different set of issues compared to foundations (Shah 2011). For example, while Rio Tinto, one of the largest global mining firms, is justifiably proud of its success in confronting malaria in Equatorial Africa, it has at the same time, dumped billions of tons of toxic waste in Papua New Guinea. Similarly, Coca Cola's global distribution system has enabled more effective distribution of oral rehydration salts for diarrhoea, a major killer of children, particularly in Africa, but on the other hand, Coca Cola and other producers of modified, unhealthy fast foods are also contributing to the burgeoning NCD epidemic in developing countries.

Foundations have always based their giving on personal perspectives of their founders and subsequent leaders. They rarely consult public health leaders in determining these goals. With the influx of large sums of money by a few foundations, this approach can very easily distort the public health agenda globally and nationally as well as the role of smaller foundations.

Large donations by private industry to international organizations like the WHO create an inherent dilemma for the latter. With over 80 per cent of its budget coming from industry, the WHO has limited flexibility to focus funds on its own priorities. In 2004–2005, WHO ended up spending 61 per cent of its budget on illnesses that accounted for only 11 per cent of global mortality because that was where the funds that were being donated were requested to be directed.

At a national level, large donations can dwarf the total budget of the recipient country and cannot be matched by the local government in many resource-constrained settings. The concern is that the local public health agenda could end up being determined by external agencies which is a particular problem when the donor's agenda is not aligned with the country's priorities, and diverts scarce resources such as trained personnel and infrastructure to lower priorities. Donor programmes often offer higher salaries which draw staff out of the public sector, leaving fewer staff within government to work on other health priorities resulting in deterioration of other important public health programmes and exacerbating the existing public health human resource crisis extant in most developing countries. For example, in Haiti, the dramatically improved HIV/AIDS situation, facilitated by private funding, has been associated with a parallel decline in other measures of the population's health, including infant mortality rates (Farmer and Garrett 2007).

Notably in these settings local government funding typically is less than 5 per cent of total government expenditures. External funding can therefore perpetuate underfunding of health and undermine the responsibility that the government takes for healthcare delivery in their country. In countries with entrenched non-functioning bureaucracies and corruption, donor funds could exacerbate corruption as funds are diverted from their intended purpose to benefit some government officials.

There are clear advantages to private funding being directed at specific public health challenges and emergencies. This has enabled eradication of smallpox, substantial increases in childhood immunization coverage, and catalysed improved responses in natural disasters or emergency situations. This type of funding works well when there are mutually agreed priorities among the various stakeholders, and involve quick and nimble investments for a short duration while the parties responsible work on plans and systems to address longer-term sustainability issues.

In relation to long-term sustainability in this context, there are at least four inter-related concerns.

Firstly, when private donations are not synchronized with global or local priority setting and are targeted at chronic conditions which require a long-term investment such as AIDS, withdrawal of funding could result in a sharp worsening of the situation. In the case of AIDS, for example, an interruption in drug supplies could lead to treatment interruptions and promote the emergence of drug-resistant strains of HIV.

Hence, significant private funding initiatives with a specific long-term focus, for example, eradication of poliomyelitis or development of a new drug or vaccine, need to be sustained until the goal is achieved for such investments to be effective.

A second area where issues of sustainability are a concern with private funding relates to a foundation having a diverse portfolio. Specifically, the concern here relates to the withdrawal of funding before the goal is achieved or the shifting of funds from one incomplete initiative to a new one. While in the corporate world, this type of prioritization and re-prioritization is typical, such an approach could be counterproductive when addressing a multitude of public health challenges. As an illustration, the Gates Foundation provides 17 per cent of the global budget (US\$86 million) to eradicate poliomyelitis, support childhood immunization programmes, develop an AIDS vaccine and microbicides, and pre-exposure prophylaxis studies. In addition, its funds support the Grameen Foundation that uses microfinance loans to empower women in Bangladesh. In partnership with The Rockefeller Foundation, the Gates Foundation supports novel agricultural practices in developing countries to enhance food security. All of these initiatives are important long-term projects with uncertain outcomes. When and how decisions will be made to continue or stop investments will have a critical and wide-ranging impact.

A third area of concern relates to who and how priorities are identified, particularly in settings with multiple challenges. For example, some express concern that the substantial funding in AIDS treatment is at the expense of HIV prevention or other health priorities. Others view it as an opportunity to concurrently strengthen healthcare delivery systems and integrate services notably for TB, maternal health, and infant health, resulting in an overall benefit to all health services. As AIDS funding focuses disproportionately on infant, maternal, and adult morbidity and mortality patterns, any gains will immediately translate to better disease burden outcomes in these settings and less to building essential health infrastructures.

With the global efforts to treat AIDS patients a new and major partner has been the pharmaceutical industry. The unprecedented price cuts and negotiation of intellectual property rights have been laudable and quoted as an example for extension to other diseases and products. Capacity building and technology transfer to less developed economies is viewed as a major opportunity to enable national governments in developing countries to meet the needs of their populations, as opposed to drug donations that meet short-term needs but create longer-term dependence.

A fourth level of concern is the lack of harmonization among donors at a country level.

In some countries, there are so many donors, each with their own agenda, that coordination and alignment to national priorities becomes very difficult. The disparity is further exacerbated if

corruption is rife. A more critical issue relates to the diversion of critical human resource capacity away from government-identified priorities to donor priorities. The duplication of services by multiple funders also creates redundancy and inefficiencies.

External investment in a country's health should prioritize partnering with improving and supporting existing public infrastructure, and should recognize that a country's government would generally be in a better position to judge its health priorities than an external organization based in a rich country (Widdus 2003). This of course assumes that the national government is well functioning and capable of determining its priorities.

In some developing countries, in the absence of local acceptable leadership, the UN agencies have assumed a leadership role and private funding and bilateral donor aid gets channelled through these structures at a country level, bypassing the appropriate governmental agencies and thus creating a situation where the government may block access to the target of these charitable organizations.

HIV/AIDS provides another example of harmonization at a country level. All the UN agencies have been part of the 'Three Ones' agreement: *one* agreed-upon HIV/AIDS action framework that provides the basis for coordinating the work of all partners; *one* national AIDS coordinating authority, with a broad based multisector mandate; and *one* consensus for country-level monitoring and evaluation system (WHO 2004). Similar agreements are needed for donor-supported health projects in general.

China provides a unique example of how government authoritarianism has helped achieve this kind of coordination. Although it was motivated by a different purpose, China insists that large donor agencies have government approval before being allowed to work in-country, and thus, the relevant officials have been able to have a direct role in deciding where and how donor money should be channelled. In South Africa, in contrast, during the Mbeki AIDS denialist era, it was private and donor funding channelled through non-governmental and academic institutions that ensured access to antiretroviral treatment for the millions dying from AIDS.

Moving forward

The generous giving of the foundations, industry, and private donors has benefited public health greatly. They have sometimes also had unintended negative consequences. How can the positive impact of private giving be maximized? A few suggestions for strategies that may contribute to this goal include:

- ♦ Objective assessment of priorities against defined and objective criteria.
- ♦ Transparency and communication with key stakeholders on priority setting.
- ♦ Consideration should be given to the short- and long-term impact of investments.
- ♦ Investment should build capacity at a national level for sustainability of investments.
- ♦ Ongoing internal monitoring of progress and periodic evaluation of the impact of the programme by an external group.
- ♦ Establishment of advisory committees that include both international and local experts.

- ◆ Partnering with key stakeholders to ensure harmonization and synergy if there are multiple investors.
- ◆ Development of transparent governance mechanisms, policies, and procedural frameworks.
- ◆ Sustained funding commitment for long-term issues.

Many of these recommendations have already been incorporated in the GFATM. As we move forward and the role of private funding continues to grow, it is important that the strengths of private giving such as focus, nimbleness, innovation, risk-taking, and efficiencies do not get lost in massive, ineffective, and paralyzing bureaucratic structures. To achieve the full potential of private giving, it is critical that it is structured to produce the maximum good with the fewest negative consequences.

The future of international public health in an era of austerity

Margaret Chan and Mary Kay Kindhauser

Introduction to the future of international public health

Since the twenty-first century began, the drive to improve health has experienced unprecedented commitments, opportunities, innovations, successes, setbacks, and surprises. Health also faces new threats arising from the radically increased interdependence of nations and policy spheres. The forces driving these changes are powerful, virtually universal, and almost certain to shape the public health agenda for years to come.

This chapter provides an overview of the remarkable progress of public health during the first decade of the twenty-first century, despite setbacks from global crises. It explores complex threats to health and emphasizes public health solutions that are either already under way or that need urgently to be pursued. The chapter concludes with a description of trends in the way public health is conceived, organized, and delivered, as reflected in new approaches to health development and new instruments for global health governance. These recent developments are cause for optimism that the momentum for better health that marked the start of this century will continue.

A decade of remarkable progress

The twenty-first century began well for public health. Leaders of 191 nations signed the Millennium Declaration in 2000 and committed themselves to reaching its eight goals by 2015 (United Nations (UN) 2000). With poverty reduction as an overarching objective, the Millennium Development Goals (MDGs) represent an ambitious attack on human misery, including that caused by disease and poor health. Three of the goals aim to reduce the mortality caused: by AIDS, malaria, tuberculosis, and other infectious diseases; by diseases of childhood; and by complications of pregnancy and childbirth. Other goals, for nutrition, education, gender equality, and the environment, including water supply and sanitation, tackle some of the most important determinants of ill health and premature death, especially in low-income settings. The final goal calls for the development of partnerships, including cooperation with pharmaceutical companies, to provide affordable access to essential drugs in developing countries.

The results have been remarkable (World Health Organization (WHO) 2012a). The incidence of new HIV infections has declined, as have deaths from malaria and tuberculosis (UN 2013). Mortality in children under the age of 5 dropped by more than 40 per cent from 1990 to 2011, and continued to decline year after year at accelerated rates (United Nations Children's Fund 2012). After decades of stagnation, maternal mortality rates dropped by 47 per cent from 1990 to 2010 (WHO 2012b). Although many countries will not reach the health-related MDGs by the target date of 2015, the overall achievements to date support the conclusion that aid for health development is working. They show the value of concentrating development efforts on a limited number of time-bound objectives that can be monitored and measured.

The MDGs are not, however, the only public health achievements of recent years. Life expectancy has risen globally for both men and women, a gain of more than 10 years since 1970, to a global average of 70 years in 2011 (*The Lancet* 2012; UN Department of Economic and Social Affairs 2012a). The WHO South East Asian region has seen a gain of more than 8 years in only the past two decades. By the next century, global life expectancy is projected to be above 80 years. Furthermore, rates of illness and death caused by infectious diseases are decreasing, as are rates of maternal illness and child mortality (WHO n.d. a).

Recent challenges

Improvements in global health are nevertheless fragile. Progress against infectious diseases is constantly threatened by antimicrobial resistance, as illustrated by the growing problem of multidrug-resistant (MDR) and extensively drug-resistant (XDR) tuberculosis. Long-standing public health challenges continue to persist particularly in low- and medium-income countries. These include the inadequate provision of safe water and safe waste disposal which contribute to childhood mortality, the burden of occupational diseases which constitute a major cause of morbidity in developing countries, environmental pollution and its acute and long-term health consequences especially in heavily-polluted cities, and violence, both interpersonal and armed conflict, which continues to be a major cause of mortality and morbidity particularly among the young in developed and developing countries.

More broadly, new dangers arise from a world of radically increased interdependence. A crisis in one part of the world can spread quickly and have profoundly inequitable consequences, adversely affecting countries that had nothing to do with the causes of the crisis. The international systems that govern trade, financial markets, and business relations can have a larger effect on the lives and opportunities of citizens, including the chances they have to enjoy a healthy life expectancy, than the policies of their governments.

The financial crisis of 2008 was a jolt, changing the global economic outlook from prosperity to austerity. The consequences on national health budgets and international aid for health development are still being felt. The drive to improve health, especially of the poor, has been severely tested. Some resource-intensive health initiatives have suffered funding shortfalls. For example, in its June 2012 report, the Independent Monitoring Board of the Global Polio Eradication Initiative concluded that the primary risk to the initiative was its precarious financial position (Independent Monitoring Board of the Global Polio Eradication Initiative 2012).

Since the global financial crisis began, many traditional donors of development assistance have come under increasing pressure to demonstrate that investments in health development elsewhere bring measurable results at home. Nevertheless, the momentum for better health has continued, including an emphasis on greater efficiency in the delivery of health services and frugal innovations that aim for simplicity, ease of use, and affordability; and the development of new initiatives, such as the UN Strategy for Women's and Children's Health, an accountability framework for tracking resources and measuring results.

In recent years the world has also woken up to the profound challenges posed by chronic non-communicable diseases (NCDs), including heart disease, stroke, diabetes, cancers, chronic respiratory disease, and mental health issues. Although NCDs were not recognized as a major threat to development when the MDGs were conceptualized, they have rapidly increased in prevalence and prominence.

Responding to the challenge of these diseases, particularly through prevention, will require major changes in the public health mind set and in the organization of health services, which, in most parts of the developing world, are geared towards the control of infectious diseases. These trends are moving public health into a new political space that deals with transnational threats to health and addresses determinants that lie well beyond the traditional concerns of the health sector.

Potential opportunities

Although the financial crisis will likely have an impact on health for some time to come, new initiatives, continuing innovations, and a quest for new sources of funding, show that the drive to improve health is still strong. Other signals come from the ethical principles embodied in some of the most successful global health initiatives and public-private partnerships formed to develop new methods of prevention and treatment for diseases of the poor. The GAVI Alliance, for example, works on the basis that every child deserves the best vaccines available, regardless of where the child was born or the income status of their parents. Product-development partnerships, such as the Medicines for Malaria Venture and the Meningitis Vaccine Project, seek to address the lack of incentives to develop new products for diseases

that mainly affect the poor by pioneering ways to bring such badly needed yet unprofitable drugs to market. In the largest sense, all of these initiatives represent a striving for greater fairness in access to the benefits of medical progress.

The international public health community has also increasingly agreed on treaties, regulations, codes of practice, and political declarations as instruments of global health governance, even in areas where public health policies are perceived as threats to powerful economic interests. The ability to reach agreement on these instruments, some of which are legally binding, such as the International Health Regulations (IHR), demonstrates the high priority given to health matters. They also reflect appreciation for the transnational nature of many of today's most important health challenges, and the need for collective action against common threats.

Public health has not always endured adverse world events with such resilience. The Declaration of Alma Ata, which launched the Health for All movement in 1978, was followed almost immediately by an oil crisis, a global recession, and the introduction of structural adjustment programmes that shifted government budgets away from social services, including health (Chan 2008). Largely as a result of these events, the 1980s became known as the 'lost decade for development'. Against this backdrop, the current determination to maintain the momentum for better health in an era of almost universal austerity appears all the more remarkable.

A health landscape of unprecedented complexity

Public health in the twenty-first century faces challenges of unprecedented complexity, with causes and consequences that extend well beyond the health sector. Foremost among these challenges is the rise of chronic NCDs, which have overtaken infectious diseases as the leading cause of mortality worldwide (WHO 2011a). This shift has its roots in demographic ageing; rapid urban growth; industrialization of food production; globalized marketing and the ready availability of highly processed foods, sugary beverages, and tobacco products; and the revolution in information technology, which contributes to increasingly sedentary lifestyles.

In addition, phenomenal increases in the speed and volume of international travel and trade have made emerging and epidemic-prone diseases a much larger threat. The demand for healthcare is rising rapidly at a time when the training and retention of doctors and nurses has stagnated, resulting in a shortage of more than 4 million healthcare workers worldwide, especially in Asia and Africa (WHO 2006). Globalization has contributed to the exodus of large numbers of health workers from the countries that invested in their training. The complex landscape of public health is also overcrowded. The proliferation of global health initiatives has created new challenges for distributive efficiency and the overall effectiveness of aid. This is particularly apparent in the added burden that multiple agencies, implementing health programmes within countries, place on already weak infrastructures and capacities.

These new challenges are superimposed upon traditional and long-standing barriers to better health—weak health systems, enduring poverty, and endemic infectious diseases closely associated with poverty.

Health in a world of growing inequalities

Health in its own right is of fundamental importance and, like education, is among the basic capabilities that give value to human life (Sen 1999). It is also a central driver of poverty reduction and socioeconomic development. The promotion of health-related human rights is a core value within the UN and WHO, and endorsed in many human rights instruments. These rights depend on the provision of social and economic human rights, such as the right to food, housing, work, and education. Health-related human rights underscore all efforts to ensure fair access to health-care for all.

Health is also a central element of human security. As the WHO Constitution notes, 'Unequal development in different countries in the promotion of health and the control of disease, especially communicable disease, is a common danger' (WHO 2005). Humanitarian emergencies, including natural and human-made disasters, infectious disease outbreaks, environmental hazards, conflicts, and the deliberate use of biological agents to incite terror, are traditionally considered the main threats to health security worldwide. However, wider considerations of human security, with the individual as a focus, also encompass issues of safe food and water, adequate shelter, clean air, poverty-related threats, violence, and the adverse effects of climate change on health (Ogata and Sen 2009). The Commission on Social Determinants of Health issued recommendations for addressing these and other threats to health that arise from the way societies are organized and governed (WHO 2008a).

Evidence is mounting that gaps, within and between countries, in income levels, in opportunities, and in health outcomes, life expectancy, and access to care, are now wider than at any time in recent history. The difference in life expectancy between the richest and poorest countries exceeds 40 years. Women in Afghanistan have a lifetime risk of maternal death of one in eight compared with one in 47,600 in Ireland. In Mali, one in five children die before the age of 5, whereas in Japan, the corresponding figure is three per 1000 live births (WHO 2012c). Annual government expenditures on health range from as little as \$1 per person to nearly \$7000 (WHO 2010a). In the decades before the 2008 financial crisis, in the Organisation for Economic Cooperation and Development (OECD) countries, the average income of the richest 10 per cent was about nine times that of the poorest 10 per cent, the largest gap in 50 years (OECD 2011a). These findings counter the assumption that the benefits of economic growth will automatically trickle down to the disadvantaged. They also suggest that the social contract is unravelling in many countries (Gurria 2011).

Decades of experience have shown that the world will not become a fair place for health by itself. Health systems will not automatically gravitate towards greater equality or naturally evolve towards universal coverage. Decisions aimed at increasing a country's economic growth will not automatically protect the poor or promote their health. International trade agreements will not, by themselves, guarantee food security, job security, health security, or access to affordable medicines. All of these outcomes require deliberate policy decisions that place equity at the forefront (Blas and Sivasankara Kurup 2010).

Social inequalities, including inequalities in health outcomes and in access to services, matter in ways that go beyond issues

of human rights and social justice. Equality contributes to social cohesion and stability. Societies with the greatest equality have the best health outcomes, irrespective of the level of government expenditure on health. Equity-focused policies for improving child survival, health, and nutrition not only accelerate progress but also do so in a cost-effective way (Carrera et al. 2012).

Demographic change: an older world population concentrated in cities

Populations around the world are experiencing unprecedented demographic change. With the world population now standing at 7.2 billion, another 2.4 billion could be added by 2050 (UN Department of Economic and Social Affairs 2012b). Behind these numbers lie other important demographic trends common to many countries. Overall, women are bearing fewer children, people are living longer and healthier lives, populations are ageing, and increasing numbers of migrants are moving from rural areas to cities and from one country to another in search of better opportunities (UN Department of Economic and Social Affairs 2012c). A sharp contrast exists between the poorest nations—with their rapidly growing and young populations, and the richer nations, with their near-zero population growth and large numbers of elderly who have chronic diseases associated with ageing.

The trend towards ever-older populations is now universal. Worldwide, the proportion of older people in the total population is increasing at more than three times the overall population growth rate. Populations are ageing fastest in low- and middle-income countries. A transition towards an older society, which took place over more than a century in Europe, is now taking place in less than 25 years in countries like Brazil, China, and Thailand. By 2017, for the first time in history, the population of people aged 65 and older is expected to outnumber children under the age of 5 (WHO 2012d). These trends have major implications for healthcare, including its costs, especially as most elderly people will eventually develop multiple co-morbidities.

Rapid urbanization is another universal trend. By 2030, an estimated six out of every ten people will be living in towns or cities, with the most explosive growth expected in Asia and Africa. For a growing proportion of the world's population, prospects for a healthy life are tied to living conditions in cities. When cities are planned, managed, and governed well, life flourishes and health outcomes are better than those seen in rural areas. However, cities also concentrate risks and hazards for health, magnifying some long-standing threats to health and introducing others. When large numbers of people are linked together in space and connected by shared services, the consequences of adverse events—contamination of the food or water supply, high levels of air or noise pollution, a chemical spill, a disease outbreak, or a natural disaster—are vastly amplified.

Cities also tend to promote unhealthy lifestyles, such as 'convenient' diets that depend on inexpensive and readily available processed foods, sedentary behaviour, tobacco use, and the harmful use of alcohol and other substances. Many of these lifestyle choices contribute to obesity and the growing prevalence of NCDs, conditions that are increasingly concentrated among the urban poor. Poverty, which in previous centuries was greatest in scattered rural areas, is now heavily concentrated in cities.

In many countries, urbanization has outpaced the ability of governments to build essential infrastructures, and to enact and enforce legislation that makes life in cities safe, rewarding, and healthy. More than 800 million people worldwide, or one in three urban residents, live in slum conditions with inherent health problems resulting from rapid unplanned urbanization (WHO Centre for Health Development n.d.). Although more than 90 per cent of urban slums are located in the developing world, nearly every city everywhere has pockets of extreme deprivation side by side with areas of extreme wealth. In every part of the world, certain city dwellers suffer disproportionately from poor health, and these inequalities can be traced back to differences in their social and living conditions. Effective urban governance is needed to deal with these problems. In developing countries, the best urban governance can help produce 75 years or more of life expectancy. With poor urban governance, life expectancy can be as low as 35 years (WHO 2010b).

The rise of chronic non-communicable diseases

Long associated with affluent societies, today NCDs disproportionately affect the poor. The WHO estimates that 36 million deaths worldwide in 2008 were caused by NCDs, primarily cardiovascular diseases, cancers, diabetes, and chronic respiratory diseases. Of these deaths, nearly 80 per cent occurred in developing countries. Nine million occurred before the age of 60, countering the belief that these are diseases of 'old age' (WHO 2013a).

The health impacts of NCDs affect all countries, but are most severe in the developing world, where health services are ill-prepared to deal with the demands of chronic care; health budgets are already overstretched; systems for financial protection are weak or non-existent; and the costs of care, usually paid out-of-pocket, tend to delay patients from seeking treatment until the disease has reached an advanced stage that is more difficult and costly to manage. For diabetes, which has reached epidemic proportions in urban parts of Asia, studies show that patients there develop the disease sooner, are more seriously ill, and die earlier than their counterparts in Europe and North America (Yoon et al. 2006).

Four shared risk factors are responsible for a considerable proportion of the burden of chronic diseases: energy-dense, nutrient-poor diets that rely on the low price and convenience of highly processed foods; tobacco use; the harmful use of alcohol; and inadequate physical activity. An intervention that modifies one of these risk factors can reduce the risk for several diseases.

The long time lag between the development of high population levels of risk and the emergence of population-wide disease further supports the importance of early intervention to reduce risk factors, especially in poorer countries where they tend to be neglected in the face of competing health needs. The exceptionally high costs of these diseases to national economies over a sustained period of time provide yet another compelling reason to focus on prevention. In some countries, the costs of caring for diabetes alone consume nearly 15 per cent of the national health budget (Zhang et al. 2010). The costs to individual households are equally devastating. The WHO estimates that, in most low- and middle-income countries, patients with diabetes, who live on US\$1 or US\$2 per day respectively, would need to spend between 25 per cent and 50 per cent of their monthly income to buy one vial of insulin from a private pharmacy (Barceló et al. 2003).

The WHO stresses the importance of taking a life-course approach to prevention, starting at the very beginning of life. Evidence is mounting that undernutrition during gestation and early childhood increases the risk of NCDs, especially cardiovascular disease and diabetes, later in life (Boekelheide et al. 2012).

Early detection and management are equally important as a strategy for reducing both the disease burden and the costs to economies. In 2011, the WHO and the World Economic Forum identified a core set of 'best buy' interventions for the prevention and control of NCDs, ranging from counselling and drug therapy for cardiovascular disease to measures to prevent cervical cancer. These are interventions that have significant public health impact, and are highly cost-effective, inexpensive, and feasible to implement (WHO and the World Economic Forum 2011).

Threats from the constantly evolving microbial world

Infectious diseases cause two main categories of threats to public health. The first category occurs in populations at risk from endemic infectious diseases, including AIDS, tuberculosis, malaria, pneumonia, diarrhoeal diseases, the neglected tropical diseases, and sexually transmitted diseases. These diseases cause high morbidity, disability, and mortality, and their control has been given high priority by national governments and the international community. Most have effective, often low-cost interventions for prevention or treatment, and many now benefit from global health initiatives established to deliver these interventions. With the sole exception of disease eradication, gains against infectious diseases are always fragile. Recent gains against nearly all of these diseases, but most especially those targeted by the MDGs, can be undone by complacency that leads to diminished control efforts or lapses in vigilance, or by the development of antimicrobial resistance.

The second category of threats, which is of more direct concern to global health security, arises from emerging and re-emerging epidemic-prone diseases, especially those that travel efficiently internationally and result in pandemics. Factors that may enhance the transmission of such diseases include increased population movements through international travel or migration or in response to disasters; growth in international trade in food and biological products; social and environmental changes linked with urbanization, deforestation, and a changing climate; the development of sophisticated new medical procedures; and changes in animal husbandry and the industrialization of food production (Ong and Heymann 2007). Many of the diseases in the first category of threats can become epidemic-prone if they are not comprehensively addressed. The development of antimicrobial resistance may result in 'super-bugs' that can quickly spread and result in epidemics. For example, bacteria containing the New Delhi metallo- β -lactamase-1 (NDM-1) enzyme are resistant to nearly all antibiotics. Common infections caused by bacteria with NDM-1 may therefore become life-threatening (Nordmann et al. 2011).

The 2003 outbreak of severe acute respiratory syndrome (SARS) demonstrated how much the world has changed in terms of its vulnerability to emerging diseases. SARS spread rapidly along the routes of international air travel and caused significant economic losses and social disruption well beyond the outbreak zones. As the emergence of diseases is tied to fundamental changes in the way humanity inhabits the planet, more novel infectious diseases

can be anticipated. Two recent examples of new infectious diseases include avian influenza A (H7N9) (Gao et al. 2013) and the Middle East respiratory syndrome coronavirus (MERS-CoV) (Bermingham et al. 2012).

A crisis in human resources for health

The WHO estimates that the world faces a shortage of 4.2 million doctors, nurses, and other healthcare staff, with 1.5 million needed in Africa alone. Of the 57 countries with the most critical shortages, 36 are in sub-Saharan Africa. This part of the world accounts for 11 per cent of the global population and 24 per cent of the global burden of disease, but has only 3 per cent of the world's health workforce (WHO 2006) (Fig. 11.13.1). The shortage is felt by nearly all countries, but has its most severe impact in the developing world, where it jeopardizes the delivery of essential, life-saving health services, including childhood immunization, care during pregnancy and childbirth, and access to treatment for AIDS, tuberculosis, and malaria. The inadequacy of human resources for health significantly correlates with higher rates of maternal mortality, infant mortality, under five mortality (Anand and Barnighausen 2004), and poorer childhood vaccination coverage (Anand and Barnighausen 2007). Survival declines proportionately as the number of health workers declines. The effect is even more acute in the growing number of countries that face a double burden of infectious and NCDs.

The causes of these shortages are manifold. Years of underinvestment have left many developing countries with limited capacity to train healthcare workers. Decades of economic and sectoral reform capped expenditures, froze recruitment and salaries, and restricted public budgets, resulting in unattractive work conditions with poor facilities, frequent drug stock-outs, inadequate equipment and supplies, shortages of support personnel, large numbers of patients with little capacity to pay, and few opportunities for career advancement (Narasimhan et al. 2004).

In Africa, medical graduates in several countries decline to work in rural areas because of lack of clinical support (Mullan et al. 2011). Moreover, the orientation of training, based on Western medicine, is often poorly aligned with the health needs of populations in the developing world.

'Push and pull' forces operate to encourage health workers to leave rural and lower-resourced areas to work under the more favourable conditions of urban employment or to seek employment abroad, a trend accelerated by the globalization of labour markets. Within countries, the discrepancy in salaries between regular public sector jobs and comparable jobs with the private sector or better-funded global health initiatives has exacerbated the human resource crisis (Vujicic et al. 2004; Atun et al. 2008). In sub-Saharan Africa, which has few opportunities for postgraduate medical education, many graduates seeking advanced training travel to Europe and North America, and many do not return (Mullan et al. 2011). The relative shortage of health workers is also exacerbated by rising demand for healthcare in many countries. The Global Health Workforce Alliance was established by the World Health Assembly in 2006 to provide a common platform for action to address these problems (Global Health Workforce Alliance n.d.).

International migration of the health workforce is a multifaceted public health challenge that has elicited intense debate. Some view the recruitment of foreign health workers as the only way for wealthy countries to cope with rising demand for healthcare. Some stress the right of health workers to migrate to countries that offer better conditions of work and pay and better opportunities to use their skills and advance their careers. Others point to the need to balance the rights of individual health workers to migrate with the right of people in the developing world to receive essential healthcare. In addition, widespread concerns have been raised about unethical and unfair recruitment practices. In response to this crisis, the World Health Assembly adopted a *Global Code of*

Fig. 11.13.1 Healthcare worker distribution by level of health expenditure and burden of disease, WHO regions.

Key: AFR, Regional Office for Africa; AMR, Regional Office for the Americas; EMR, Regional Office for the Eastern Mediterranean; EUR, Regional Office for Europe; SEAR, Regional Office for South-East Asia; WPR, Regional Office for the Western Pacific.

Practice for the International Recruitment of Health Personnel in 2010, after nearly 6 years of debate (WHO 2010c). Compliance with the code is, however, voluntary; monitoring is under way to assess its effectiveness.

A shrinking arsenal of safe and effective medicines

The overuse, underuse, and misuse of antibiotics, in both human and veterinary medicine, have accelerated the emergence and international spread of drug-resistant pathogens. The speed with which the therapeutic arsenal of antimicrobials is shrinking far outpaces the development of replacement drugs, which are regarded by the pharmaceutical industry as less lucrative than medicines for chronic conditions, and less likely to have a long market life owing to the rapid emergence of resistance. These trends raise the spectre of a post-antibiotic era in which many common infections will no longer have a cure and, once again, kill unabated. The implications extend to many other life-saving and life-prolonging interventions. Some sophisticated interventions, such as joint replacements, organ transplants, cancer chemotherapy, and care of preterm infants, would become far more difficult or even too dangerous to undertake without effective antibiotics.

Replacement treatments for first-line antimicrobials that have lost their effectiveness are more costly and more toxic and require much longer durations of treatment, including hospital-based treatment. Studies have documented higher mortality among patients infected with drug-resistant pathogens. Among the world's 12 million tuberculosis cases in 2010, the WHO estimates that 650,000 involved MDR tuberculosis strains. Treatment of MDR tuberculosis is challenging, typically requiring 2 years of medication with toxic and expensive medicines, some of which are constantly in short supply. Even with the best of care, only slightly more than 50 per cent of these patients will be cured (WHO 2012e). The emergence of malaria parasites resistant to artemisinins, the last remaining class of effective drugs for the treatment of malaria, counts among the greatest fears of public health today. Evidence of resistance to artemisinins on the Cambodia–Thailand border, the historical epicentre for the emergence of drug-resistant malaria parasites, was confirmed in 2009. In 2011, the WHO launched an ambitious global plan to stop the further emergence of artemisinin-resistance at its source, and thus prevent, or at least significantly delay, further international spread.

Many other pathogens are developing resistance to multiple drugs—some pathogens like gonorrhoea and typhoid fever to nearly all drugs. Hospitals have become the breeding ground for highly resistant pathogens, such as methicillin-resistant *Staphylococcus aureus* (MRSA), extended spectrum beta-lactamase-producing (ESBL) bacteria, and carbapenemase-producing Enterobacteriaceae (CPE), increasing the risk that hospitalization kills instead of heals. Many are now found in the community, increasing the risk to health. To raise awareness and action, the WHO made combating antimicrobial resistance a priority at World Health Day 2011, and has since strengthened the initiative towards a long-term agenda to combat resistance through multipronged approaches.

The supply and trade of counterfeit and substandard medicines is another growing problem with international dimensions that compromises the quality of healthcare. The true scale of the problem is poorly documented, but some estimates suggest that 10–30 per cent of medicines on sale in developing countries

are substandard or counterfeit (Cockburn et al. 2005). All countries are affected, as most recently demonstrated by tainted steroids in the United States that caused several deaths and placed 13,000 people at risk (Centers for Disease Control and Prevention 2012). The consequences can be severe. In Pakistan, more than 100 patients died following administration of contaminated cardiovascular medication (WHO 2012f). Countries that lack strong drug regulatory authorities and quality control laboratories are at particular risk. Substandard medical products may arise from unintentional lapses in good manufacturing practices. Other medical products of concern may enter the market from unknown or unlicensed producers and thus prove very difficult to trace. A known or licensed producer may intentionally distribute a substandard product as, for example, a product with a falsified expiration date or statement of active ingredients. Still other medical products may be deliberately and deceptively formulated and packaged to imitate another product often in very sophisticated ways. Drugs falsified in this way are copyright infringements and violations of intellectual property rights. While such instances are criminal activities to be addressed in appropriate courts of law, public health must be concerned whenever substandard or dangerous medicines enter the supply chain, regardless of whether the cause reflects deliberate deception, negligence, or weak capacity for quality assurance and regulatory control.

The drugs most commonly falsified include antimicrobials, hormones, and steroids. A study of malaria medicines sampled from several countries in South East Asia and sub-Saharan Africa found that 35 per cent of the samples from both regions failed chemical analysis; 46 per cent failed packaging analysis and 36 per cent were classified as falsified in South East Asia; and 35 per cent failed packaging analysis and 20 per cent were classified as falsified in sub-Saharan Africa (Nayyar et al. 2012). More recently, sophisticated and deceptive practices have included the falsification of anticancer and antiviral drugs, including those used to treat AIDS. To combat these problems, much more needs to be done to strengthen national drug regulatory authorities and quality assurance laboratories. The WHO estimates that only around 20 per cent of countries have well-developed systems for regulating medical products—of the remaining countries, around 50 per cent implement drug regulation at varying levels of effectiveness, and the remaining 30 per cent have either no drug regulation in place or a very limited capacity that barely functions. The increasing sale of medicine via the Internet further complicates efforts to protect consumers from substandard or falsified medical products (WHO n.d. b).

Past efforts to address the problem of counterfeit and substandard medicines have been hampered by the confusion of public health issues with issues of intellectual property rights and copyright infringements, and high-profile trade incidents in which legitimate generic medicines were seized, in transit, as counterfeits. In many countries, the only legal instrument available to address the public health problems caused by counterfeit and substandard medicines is legislation related to intellectual property rights, which further fuels the confusion (Attaran et al. 2012).

A changing climate

Climate change—possibly the defining issue of the twenty-first century—poses a significant addition to the spectrum of environmental hazards that threaten health. The contribution of human

activities to changes in the climate system is irrefutable. The consequences of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising average sea levels are already being felt (WHO 2008b). Climate change will affect, in profoundly adverse ways, the most basic determinants of health: air, water, food, shelter, and freedom from disease. While the warming of the planet is expected to be gradual, the effects of extreme weather events—more storms, floods, heat waves, cold waves and droughts—will be abrupt and acutely felt. Such events are expected to increase in both frequency and intensity. While climate change is a global phenomenon, scientists predict that developing countries, including those that have contributed least to greenhouse gas emissions, will experience the earliest and most severe consequences, also for health (Postigo et al. 2007).

Specific effects of climate change on health include: (1) increases in malnutrition (associated with declining food production and security, especially in areas dependent on rain-fed agriculture) and related increases in the severity of childhood infectious diseases; (2) increases in death, disease, and injury due to extreme weather events; (3) increases in the number of displaced populations and the corresponding problem of ‘environmental refugees’; (4) increases in episodes of diarrhoeal disease; (5) increases in outbreaks, especially of cholera due to unsafe water and flooding; (6) increases in the frequency of cardiorespiratory diseases associated with heat waves; and (7) altered distribution of vectors responsible for infectious diseases, most notably malaria and dengue (WHO 2008b).

In our interdependent world, the effects of a changing climate can have widespread consequences. Recent droughts in the Russian Federation and the United States significantly reduced world grain supplies. Whether these events are direct expressions of a changing climate is still being debated, but their contribution to record-breaking world food prices has been well documented, offering evidence of what lies ahead: more global crises caused by rising food prices (Food and Agriculture Organization of the United Nations 2012). The same is true for the two mega-disasters of 2010, the floods in Pakistan and the earthquake in Haiti, which outstripped the capacity of the international humanitarian community to respond. The disproportionate impact of climate change on the developing world will almost certainly further widen the unacceptably large gaps in health outcomes. Some have suggested that climate change could undo the progress made towards reaching the health-related MDGs. Unfortunately, these effects on health have been largely neglected in debates about climate change and the justifications for urgent action either to mitigate the causes or adapt to the consequences. Humanity, not only an endangered species like the polar bear, and human health should be the face of climate change.

The proliferation of global health initiatives

About 100 global health initiatives now exist—far more than in any other sector contributing to development. Most of these target health interventions for single infectious diseases or related groups of these diseases. A few, including the Global Fund to Fight AIDS, Tuberculosis and Malaria, the GAVI Alliance, the US President’s Emergency Plan For AIDS Relief (PEPFAR), and the World Bank Multi-Country AIDS Program (MAP), contribute substantially to the funding for health provided by international donors (World Health Organization Maximizing Positive

Synergies Group 2009). In addition, an increasing number of non-governmental, faith-based, and private sector organizations are delivering health programmes in countries. New philanthropies, including the Bill & Melinda Gates Foundation, have become a potent financial force supporting the quest for new medical products for diseases of the poor and the delivery of pro-poor health interventions within countries.

Some experts in development aid view this rapid proliferation of initiatives as creating a public health landscape that is overcrowded and competitive. Problems identified include fragmentation and duplication of efforts, high transaction and operational costs, and the burden on recipient countries of multiple separate demands for monitoring and reporting. For example, in 2009, Vietnam dealt with more than 400 donor missions to review health projects or the health sector. Rwanda must report annually to various donors on 890 health indicators, with nearly 600 relating to HIV and malaria alone. Although increases in funding for health development are a welcome trend, recipient countries must digest such assistance with an extraordinary mobilization of their own very limited health resources.

In parallel, efforts to scale up the delivery of interventions have brought renewed attention to pervasive weaknesses in health systems as one of the most important barriers to programme success. Single-disease initiatives depend on a well-functioning health system to achieve their objectives yet rarely make the strengthening of health systems an explicit goal. Under the pressure of scaled-up efforts to deliver interventions, long-standing weaknesses became more visible: severe staff shortages; inefficient procurement and supply chains; frequent stock-outs; little capacity to regulate the quality and availability of medicines in either the public or private sectors; weak laboratory support; a concentration of clinical services in urban areas; a reliance on user fees to finance healthcare; little or no support from social protection or insurance schemes; crumbling government-funded services that forced reliance on more expensive private providers, even for routine care; and a glaring absence of fundamental health data for setting priorities, measuring results, monitoring progress, and adjusting priorities and strategies accordingly.

The debate about whether global health initiatives strengthen or weaken health systems and distort national priorities has been intense. It rekindles a decades-old controversy over horizontal versus vertical approaches to health development, but in a more nuanced guise, as most health services now combine vertical and integrated elements, with varying degrees of balance between them (Atun et al. 2008). Some critics argue that single-disease initiatives have deepened inequalities in health services, reduced the quality of services because of pressures to meet targets, and created expensive parallel systems for the management of programme delivery, bypassing rather than strengthening existing national systems (*The Lancet* 2009). Other studies suggest that single-disease initiatives make an important contribution to improved health outcomes by delivering preventive or treatment interventions for high-mortality diseases, especially when health systems are weak, a rapid response is needed, and economies of scale can reduce procurement costs and further extend coverage (Atun et al. 2008).

Evidence for the benefits of single-disease initiatives is too limited to support firm conclusions about their broad effects on health systems. Some criticisms lose their relevance as programmes

successfully reduce the disease burden and graduate to a more integrated approach. For example, the adoption of a new global health sector strategy on HIV/AIDS, 2011–2015 (WHO 2011b), stressing integration with existing health services, is regarded by many as marking a formal end to AIDS exceptionalism. Similarly, the Onchocerciasis Control Programme (WHO n.d. c) in West Africa, which began as a strictly vertical programme, with helicopters applying insecticides to fast-flowing rivers, eventually evolved to a primary healthcare approach that relies on community-directed distribution of ivermectin together with other essential interventions, including bednets, vitamin A supplements, and deworming tablets. Moreover, for AIDS, tuberculosis, and malaria, it is generally agreed that single-disease initiatives upgraded the quality of clinical care by introducing standardized treatment protocols and delivering quality-assured interventions.

Concern about the growth of uncoordinated aid and its adverse consequences has been addressed by international instruments such as the Paris Declaration on Aid Effectiveness of 2005 and the Accra Agenda for Action of 2008 (OECD 2005, 2008). These set out principles for improving the quality of aid and making development assistance more effective, with clear responsibilities for donors as well as recipient countries. A growing number of partnerships are implementing these principles in a spirit of mutual accountability and with an emphasis on delivering measurable results. In 2011, a meeting in Busan, Republic of Korea, took these commitments a step further with the concept of domestic accountability, in which country ownership matures to the point that governments are ultimately held accountable, by citizens and civil society organizations, for safeguarding public health (OECD 2011b).

In 2007, the International Health Partnership and Related Initiatives, known as IHP+, was established to accelerate better health results in low- and middle-income countries by applying principles of aid effectiveness, giving particular attention to aligning contributions from donors and implementing agencies with a country's own definition of its needs and capacities (IHP+ n.d.). The initiative has grown from 27 to 56 signatories to the IHP+ Global Compact, including 25 countries in Africa. IHP+ has developed and refined tools for improving the quality of national health strategies and plans and for conducting joint assessments of these. It has also helped bring civil society into these processes at country level, giving them a greater voice in policy formulation.

Work on harmonization and simplification of financial management has accelerated through collaboration between the World Bank, the GAVI Alliance, and the Global Fund. Other development partners are also becoming involved. Through IHP+, a single monitoring and evaluation framework with a limited number of indicators was developed, based on consultations with countries and development partners. Supported in part by the achievements of the Commission on Information and Accountability for Women's and Children's Health (WHO n.d. d), the framework is being used by a growing number of countries as the basis for strengthening their health information platforms.

The 2008 global financial crisis has changed the operating environment for IHP+. Growth in development assistance for health slowed, with data for 2011 showing a 3 per cent real decline in aid as a whole (IHP+ 2012). The number of aid providers, however, has continued to increase, increasing the risk of fragmentation. There has also been less political willingness to take risks and an increased focus on value for money. These trends reinforce the

need for the WHO and other agencies to continue to play an active role in initiatives that aim to improve aid effectiveness.

Recent experiences show the value of harmonizing and aligning development assistance, especially when country ambitions are pragmatic and show vision. For example, Nepal introduced free maternal healthcare in a few districts in 2009, and announced its plans to extend this throughout the country's 76 districts. Donors united behind this visionary plan, and the goal was achieved in 2011. In the Democratic Republic of Congo, a single-donor coordination arrangement, introduced by the Ministry of Health, reduced the management costs of donor funds from 28 per cent to 9 per cent. The funds saved were invested to expand coverage with insecticide-treated bednets.

Questions about the sustainability of funding for health development continue to be raised, and particularly in the current era of austerity. The domestic pressure on donors to demonstrate results for investments in health development may skew investments to areas that can yield rapid measurable results. In such calculations, childhood immunization, for example, wins out over the purchase of antiretroviral medication, creating fears that the expansion of coverage with antiretroviral therapy may lose momentum.

Strategies for maintaining momentum in an era of austerity

Despite the financial crisis that began in 2008, the international community has not backed away from its commitment to better health, especially for the poor. Instead, the focus has been on using new instruments and political agreements to better utilize existing resources, reduce waste and inefficiency, demonstrate the value of investments by tracing resources and measuring results, and to use legislation and regulatory control to reduce threats to health at their source. New solutions that work well for one problem are being adapted to address others. Mechanisms for ensuring that developing countries reap the benefits of research and development for new medical products are also being negotiated. Many of these instruments and political agreements operate at the international level, reflecting solidarity in the desire for greater healthcare equity and the transnational nature of many health threats. As such, they are building a framework for global health governance.

New instruments for accountability

Instruments and frameworks for accountability aim to ensure that resources for health are responsibly used and are fully accountable, that results are measured and transparently reported, and that strategies are adjusted when expected results fail to materialize. Two of these instruments are described in the following subsections: the Independent Monitoring Board of the Global Polio Eradication Initiative and an accountability framework and independent monitoring body established by the Commission on Information and Accountability for Women's and Children's Health. Independent accountability is a compelling new concept in public health and holds promise as a way of spending resources more wisely, improving outcomes and maintaining the confidence of donors and the support of ministries of finance.

Accountability for polio eradication

In 2008, there were heightened concerns that the hitherto successful global polio eradication programme would be derailed.

A devastating setback in Nigeria 5 years earlier resulted in a surge of cases in northern Nigeria, after bans on vaccination issued by religious leaders and supported by politicians. This seeded outbreaks in many countries that had previously been polio-free, necessitating intensive containment campaigns. Some of these campaigns were unsuccessful, leading to the re-establishment of transmission in new areas. Experts previously argued that polio could never be eradicated, that the goal was unrealistic, and that it was time to give up and move the programme from eradication to control (Arita et al. 2006).

By 2008, donors were fatigued, field staff were tired and discouraged, and commitment in many countries with indigenous wild poliovirus or with re-established transmission was waning. Reassuring statements that the eradication effort was in the 'home stretch' had been repeatedly issued for nearly a decade and were losing credibility, and the programme faced a funding gap of \$575 million for 2007–2008.

In 2008, the World Health Assembly responded to this alarming situation by asking the WHO to develop a new strategy to reinvigorate the drive to eradicate polio. As some delegates had noted, the strategy that had worked so well to reduce the worldwide number of cases by 99 per cent since 1988 was inadequate for the challenge of eliminating the remaining 1 per cent of cases. In an unusual step, the WHO established an Independent Monitoring Board (IMB) to monitor the implementation and impact of the new strategic plan and its milestones, covering the 2010–2012 timeframe (The Global Polio Eradication Initiative n.d.). The IMB uses data generated by the eradication initiative but independently develops its own analyses and presentations and does not share drafts of its assessments before they are finalized. Its reports have been frank in their analyses and criticisms of dysfunctions and missed opportunities at every level of programme performance, from local staff, to national strategic plans, to the administration and culture of the global programme. As an instrument for accountability, the value of the IMB has been enforced by its insistence that its recommendations are heeded.

The results have been impressive, showing a substantial impact on programme performance but also on the prospects of success.

At the start of 2012, India, arguably the most challenging of all the remaining sanctuaries of poliovirus, had been polio-free for a year. The worldwide number of new cases was at the lowest level since records began. In May 2012, the WHO, acting on a recommendation of the IMB, declared the completion of poliovirus eradication a programmatic emergency for global public health, requiring the institution of strong national oversight and accountability mechanisms for all affected areas. The programme was restructured on an emergency footing. Thousands of additional staff were recruited, and national emergency plans were launched in Afghanistan, Pakistan, and Nigeria, the three remaining countries with indigenous poliovirus. India sent its experienced staff to share best practices with other countries. More children were reached, for the first time, in high-risk areas. The IMB final report for 2012 revised downwards the percentage of cases yet to be eradicated to 0.1 per cent and concluded that the prospects for success were more positive than ever (Independent Monitoring Board of the Global Polio Eradication Initiative 2012).

Accountability for women's and children's health

The UN's Global Strategy for Women's and Children's Health, also known as Every Woman, Every Child, was launched in 2010

as the first major health initiative since the 2008 financial crisis (Every Woman, Every Child n.d.). It responded to stalled progress in reaching the MDGs for reducing child and maternal mortality. Donors initially pledged \$40 billion to support the strategy, and that amount has since increased. The strategy targets 75 countries where 98 per cent of all maternal, neonatal, and child deaths occur and includes the delivery, on a large scale, of low-cost but high-impact interventions with a proven capacity to save lives.

Every Woman, Every Child has several unique features. First, it was almost immediately followed by the establishment of a Commission on Information and Accountability for Women's and Children's Health, jointly supported by the WHO and the International Telecommunication Union. The Commission set out a framework for accountability that includes a small but balanced set of core indicators for measuring progress, supported by a tracer set of eight coverage indicators that can monitor almost real-time changes in coverage. Second, the development of systems for reliable civil registration and vital statistics was a built-in component of the framework. Finally, an independent Expert Review Group was rapidly established to provide oversight, including the identification of best value-for-money approaches.

The Expert Review Group operates with full independence. Its first report expressed serious concerns about the failure of some promised resources to materialize, the continuing absence in 64 of the 75 countries of reliable data on the key indicators established by the Commission, and insufficient progress overall (Independent Expert Review Group on Information and Accountability for Women's and Children's Health 2012). The report made six recommendations for improving the effectiveness of the accountability framework. Predictably, the report found that 53 of the 75 priority countries suffer a severe shortage of health workers, and recommended that the strengthening of human resources for women's and children's health be addressed as a matter of immense urgency. The accountability framework for Every Woman, Every Child has proved broadly useful for other health initiatives, including the International Health Partnership and Related Health Initiatives. The framework's country monitoring and evaluation platform is used by the Global Fund and the GAVI Alliance and has influenced the framework for the global monitoring of chronic NCDs.

New instruments for global health governance

Since the start of this century, the international health community has agreed on an unprecedented number of treaties, regulations, and codes of practice aimed at improving the global governance of public health by introducing systems of rules-based obligations. Some are legally binding 'hard law' instruments. Others are voluntary 'soft law' agreements. All respond to challenges that have international dimensions and depend on broad collaboration for an effective response. Some of these are described in the following subsections.

Framework Convention on Tobacco Control

The Framework Convention on Tobacco Control (FCTC), which came into force in 2005, is the first treaty negotiated under the auspices of the WHO and one of the most rapidly ratified treaties in the history of the UN (WHO Framework Convention on Tobacco Control 2012). The legally binding treaty now has 171 signatories representing nearly 90 per cent of the world's population.

Provisions in the treaty provide rules governing the production, sale, distribution, advertisement, and taxation of tobacco products as minimum requirements for tobacco control. The FCTC and a related treaty that followed, the Protocol on the Elimination of Illicit Trade in Tobacco Products (WHO Framework Convention on Tobacco Control 2013), demonstrate what can be achieved when multiple sectors, including trade, finance, agriculture, education, labour, the environment, law enforcement, and the judicial system, collaborate in the name of health.

International Health Regulations

The revised International Health Regulations (IHR) came into force in 2007 (WHO 2008c). Administered by the WHO, the Regulations bring an orderly, rules-based structure to the detection, reporting, and containment of public health emergencies of international concern. They also provide a centralized, coordinated mechanism for sharing information and keeping the world informed. The current, revised version of the IHR was strongly influenced by experiences during the SARS outbreak of 2003, which underscored the need for better disease intelligence and more stringent requirements for reporting. Adoption of the revised Regulations moved the response to health emergencies from a passive, reactive effort to prevent spread across national borders to a proactive effort that aims to stop an outbreak before it has a chance to spread internationally.

Recommendations on the marketing of unhealthy food and beverages

The marketing of unhealthy foods and beverages to children is a growing problem. Advertising and other forms of food marketing to children are widespread across the world (Hastings et al. 2003; McGinnis et al. 2006; Cairns et al. 2009). Most of this marketing is for foods high in saturated fats, trans fatty acids, sugar, and salt. There is evidence that television advertising, including transboundary advertising, influences children's food preferences, requests, and consumption patterns. In addition, studies have shown compelling evidence of an association between the consumption of sugary beverages and the prevalence of obesity and overweight in children and adolescents (De Ruyter et al. 2012; Ebbeling et al. 2012; Qibin et al. 2012). In 2010, with more than 43 million pre-school-aged children estimated to be overweight or obese, the World Health Assembly adopted recommendations aimed at fostering more responsible marketing practices in the food and beverage industries. Although some countries have introduced legislation or established national policies aimed at curtailing the marketing of unhealthy foods and beverages to children, the global recommendations depend on voluntary changes on the part of the food and beverage industries.

Some experts and civil society organizations believe that the recommendations do not go far enough, that industry self-regulation is unlikely to be effective, and that a legally binding international treaty or convention is needed. As support for their arguments, they cite repeated industry violations of the 1981 International Code of Marketing of Breast-milk Substitutes (International Baby Food Action Network 2010). Support for stronger measures also comes from studies comparing the behaviour of the food industry with that of the tobacco industry in the second half of the previous century. While there are many differences between these industries, such comparisons reveal the use of broadly similar tactics: making pledges of self-regulation, lobbying with massive

resources to stifle government action, introducing 'safer' products, and paying scientists to instil doubts about the conclusiveness of evidence (Brownell and Warner 2009). If the food industry does not change pre-emptively, public opinion may turn against it, as it did with the tobacco industry. At present, public health might best contribute to the debate by continuing to document the prevalence of overweight and obesity in children, to demonstrate the multiple risks and consequences for health, and to estimate the costs.

Voluntary code of practice on healthcare worker migration

The migration of health workers from the countries that invested in their training is another critical problem that requires an international solution. A global code of practice for the international recruitment of health personnel, adopted in 2010 (WHO 2010c), establishes voluntary principles, standards, and practices for the ethical international recruitment of health personnel in order to achieve a balance, in line with the principle of mutuality of benefits, between the rights, obligations, and expectations of source countries, destination countries, and migrant health personnel. Compliance with the code's voluntary principles remains to be determined.

Pandemic Influenza Preparedness Framework

In 2011, after nearly 6 years of intense negotiations, the World Health Assembly approved the Pandemic Influenza Preparedness Framework, which breaks new ground in preparing the world to respond to future influenza pandemics in more equitable ways (WHO 2011c). The framework sets out obligations for the sharing of information and materials relating to influenza viruses of pandemic potential, and of the resulting benefits, including medicines and vaccines, once a pandemic is underway. The Framework stipulates obligations for the WHO, its Member States, and WHO-appointed influenza laboratories, but also for the pharmaceutical industry, which eventually profits from the sharing of viruses when it manufactures influenza vaccines and antiviral medicines. For example, pharmaceutical companies contributed around \$28 million in 2012 to support implementation of the Framework in areas such as improving laboratory and surveillance capacities and the acquisition of medical products. Industry will make additional contributions yearly. Implementation of the Framework is overseen by an independent group of experts, continuing the trend of independent monitoring as a new norm for international public health. Although negotiations were especially tense and difficult, the resulting instrument marks an important step forward in ensuring the more equitable distribution of medical products during international public health emergencies and finding a fair way to secure a new source of funding for building capacity in the developing world.

Prospects for additional treaties

Calls for additional treaties and conventions have been made for additional transnational threats to health and other urgent problems that depend on broad-based collaboration for their solution. In 2012, two intergovernmental processes were established to consider proposals for treaties aimed at protecting countries from trade in substandard and counterfeit medicines and generating financial support for research and development in new medical products for the neglected diseases of the poor. The results of initial meetings suggest reluctance by many countries to commit to

the protracted and costly negotiations needed to reach agreement on treaties. The options do, however, remain open.

Essential medicines: strategies for improving access and innovation

The need to ensure access to safe, effective, quality-assured, and affordable medicines is a long-standing concern. The first Model List of Essential Medicines was issued in 1977 as a groundbreaking way to support countries in their efforts to rationalize procurement and prescribing practices and to focus limited purchasing power on medicines that meet the priority health needs of populations (WHO 2013b). The lists, which are updated every 2 years, are widely used in the developing world and also in some wealthy countries as the basis for insurance reimbursement schemes. Concern about equitable access peaked with the spread of AIDS—when effective antiretroviral treatments became available, and survival for many millions of patients often depended on their ability to pay. AIDS made inequitable access to medicines both highly visible and ethically unacceptable. The AIDS epidemic further demonstrated that price reductions were a feasible objective; the price of antiretroviral therapy dropped by nearly 99 per cent in less than a decade.

Better access to medical products, especially for the poor, is currently being pursued on two main fronts: reducing prices for existing products and developing new products for markets with limited purchasing power where there are few incentives for industry research and development. Financial support for the development of new medicines is largely generated by intellectual property rights and the patent regime, which protects high prices for originator products and delays the market entry of less expensive generics. Generic medicines, which do not need to recoup the considerable investments needed for drug discovery, development, and marketing approval, are sold at prices closer to the costs of manufacturing, offering a significant means to reduce health-care costs in all countries. Policies that rationalize the purchasing and prescribing of medicines can be a major source of savings in any country. In many countries, a national policy that encourages the use of generic medicines can save an estimated 60 per cent of the costs of medicines (WHO 2010a).

The WHO Prequalification Programme also operates to improve access to quality, affordable medical products. It stimulates the supply of quality-assured medicines, including generics, and encourages fair competition (WHO 2013c). The Programme was established in 2001 and initially served as a mechanism to ensure that UN agencies, the GAVI Alliance, and the Global Fund get the best quality products at the best prices for use in health campaigns. The Programme has expanded from this initial purpose and now operates in ways that allow manufacturers from developing and emerging economies to enter the market and, when strict quality and safety standards are met, to compete with established manufacturers on an equal footing. This has resulted in more abundant and reliable supplies, better forecasting, and often substantial price reductions driven by added competition, changing the dynamics of the market for medicines and public health vaccines (WHO 2012g). The programme also contributes to globally harmonized quality standards and reduces the supply of substandard products. The strengthening of capacities, including the hands-on training of drug regulators, is a central component of the programme. Strong compliance mechanisms are in

place and on-site inspections to ensure adherence to good manufacturing practices are repeated at regular intervals. Products can, and frequently do, get de-listed if quality is not maintained; the prospect of de-listing has proven to be a powerful incentive to maintain standards.

Another concern about the current patent regime is its bias towards commercially profitable products and its neglect of diseases that predominantly affect the poor. International efforts to correct the current incentive scheme that drives research and development, or at least compensate for its bias towards commercially lucrative products, have been underway for more than a decade, and featured strongly in the negotiations that eventually led to adoption of the Global Strategy and Plan of Action for Public Health, Innovation and Intellectual Property (WHO 2011d).

Public-private partnerships have emerged as a promising way to compensate for the bias inherent in the patent system. In the past, the quest for new products for neglected diseases has usually been opportunistic. Existing products, often developed for veterinary purposes, were screened for their potential efficacy in treating human diseases. More recently, this process has become strategic. An unmet health need is identified, an ideal product is defined, and a public-private partnership is formed to develop the product. These projects usually bring together expertise from academia, industry, and public health, with funding from philanthropic sources. Recent examples include the Medicines for Malaria Venture, the International AIDS Vaccine Initiative, the Global Alliance for TB Drug Development, the Drugs for Neglected Diseases Initiative, and funding from the Bill and Melinda Gates Foundation to develop a malaria vaccine.

This positive trend continues to evolve. For example, the Meningitis Vaccine Project illustrates the many ancillary benefits that can accrue when a product is designed with the needs of very poor countries in mind (Meningitis Vaccine Project n.d.). African ministers of health asked for a new vaccine that could prevent almost yearly epidemics in the 26 countries that form Africa's Meningitis Belt, and defined its ideal characteristics, including a price they could afford to pay. The project required collaboration with several commercial companies, and broke new ground in the management of intellectual property rights. The technology for producing a conjugate vaccine was transferred from the United States and the Netherlands to the Serum Institute of India, which agreed to manufacture the vaccine at the target price of 50 cents per dose. In less than a decade, the new vaccine was developed by a consortium of scientists, licensed with support from Canada's regulatory authority, and prequalified by the WHO. The vaccine protects very young children, confers immunity that may last a decade, and contributes to herd immunity. The first campaigns using the new vaccine began in late 2011; more than 100 million doses had been administered by the end of 2012. Following these campaigns, some hyperendemic countries have recorded their lowest level of meningitis cases in more than a decade. The economic benefits are expected to be significant. A single case of meningitis can cost a household the equivalent of 3–4 months of income. Mounting a reactive emergency response to epidemics can absorb more than 5 per cent of a country's entire health budget. The project is groundbreaking in another sense. African countries usually have to wait years, if not decades, for new medical technologies to trickle into their health systems. In this case,

Africa was first to receive the best technology that the world, working together, could offer.

The most ambitious initiative thus far to promote innovation for neglected diseases followed the 2012 publication of a report, commissioned by WHO Member States, which proposed mechanisms for research and development (R&D) financing and coordination that could provide a sustainable solution (WHO 2012h). An intergovernmental process was established to take forward the report's recommendations and proposals in the three broad areas of monitoring R&D flows, the coordination of R&D, and finding new, innovative, and sustainable sources of funding. The substance and form of an international agreement is currently being debated. Proposals include establishing an R&D observatory, setting up a funding instrument that pools funds at the international level, and starting negotiations on an international treaty that would commit governments to spend at least 0.01 per cent of GDP on R&D to develop new products for diseases that mainly affect developing countries.

Universal health coverage

One of the strongest signs of continuing commitment to better health comes from the number of countries that are adopting policies to extend health coverage to all their citizens. Following the publication of the World Health Report 2010, *Health Systems Financing: The Path to Universal Health Coverage* (WHO 2010a), more than 70 low- and middle-income countries have requested the WHO's technical assistance in planning strategies to move towards universal coverage. Universal health coverage is arguably the single most powerful concept that public health has to offer. It is an effective social equalizer, the ultimate expression of fairness, and one of the best ways to cement the remarkable gains made during the first decade of the twenty-first century. Universal health coverage is also a unifying concept that draws together the many factors, from access to essential medicines and social protection schemes, to preventive as well as curative care, that together ultimately influence health outcomes. As studies show, universal coverage improves the efficiency of service delivery, leads to better health outcomes, and has been effectively supported by a range of health financing reforms in several lower income countries. When countries move towards universal coverage, the benefits of interventions, when taken to scale, are value-added. They not only protect health or prevent a disease, but also bring down the risks for entire populations. In addition, economists point to considerable economies of scale in service provision when interventions reach a large proportion of the population (Sachs 2012).

Universal health coverage does, however, carry some risks. One important caveat is that there is no 'one-size-fits-all' solution. No single mix of policy options is right for every country; any effective strategy must be home-grown.

Further, when public services are free, overconsumption of healthcare is possible, especially by the rich, even though their needs may be less than those of the poor. And although removing financial barriers does help the poor obtain care, it does not guarantee it. Financial barriers, such as those incurred by transportation and accommodation costs to obtain treatment, may still exist.

Finally, improving efficiency is imperative to avoid incurring unsustainable costs. The main sources of inefficiency lie in the areas of medicines (costs, inappropriate and ineffective use, underuse of generics, use of substandard and counterfeit medicines, etc.);

healthcare products and services; human resources (inappropriate or costly mix of staff, problems with recruitment, inadequate salaries); hospitals (inappropriate admissions and length of stay, too many or too few hospitals and inpatient beds); medical errors; waste, corruption, and fraud; and inappropriate balance between levels of care or between prevention, promotion, and treatment. Sustaining universal coverage requires finding the most efficient ways to meet demands for health services (WHO 2010a).

Some commentators have described the growing prominence in health policies of universal coverage as the third great transition in health, following the demographic transition that began in the late eighteenth century and the epidemiological transition that began in the twentieth century. Many argue that universal coverage should be included as a goal in the post-2015 development agenda.

Conclusion

The landscape of public health in the twenty-first century is complex, challenging, and overcrowded. Some problems arise from the explosive growth of assistance for health development that followed commitment to the health-related MDGs. Others arise from universal trends generated by the world's radically increased interdependence. All around the world, health is being shaped by the same powerful forces, blurring the distinctions between wealthy and developing countries. Solutions need to be found that work internationally as well as within countries or regional groups of countries. Inequality is growing, resulting in demands that equity be included as an explicit objective in the policies of health and other sectors. Foremost among the new challenges to health is the growing prevalence of chronic NCDs, which have overtaken infectious diseases as the leading cause of mortality worldwide. Responding to these diseases will require transformational changes in the way public health is conceived and delivered. It will also require new strategies for addressing risk factors that reside in sectors beyond the purview of health officials. Developments in tobacco legislation reveal the promise of regulatory solutions, especially for transnational threats to health; they also show that collaboration, in the name of health, among multiple sectors is entirely feasible.

Although worldwide financial uncertainty may appear to put at risk the future of financing for health development, several recent initiatives suggest that the momentum for better health has not faltered and that innovative ways will be found to reach more people with better services at lower costs. The prominence of universal health coverage in policy debates demonstrates the priority being given to fairness, as do efforts to find financing to develop new medicines for diseases of the poor. Recent agreement on several instruments for global health governance, also in areas where public health concerns cross purposes with powerful economic interests, further signals a continuing high-level commitment to health. The establishment of independent mechanisms for ensuring accountability can potentially increase confidence that money is being spent wisely and with good effect.

Public health alone cannot fundamentally change the way the world works. But public health can and should continue to be a powerful driver of positive change that dramatically improves the health and lives of populations across the planet. The WHO takes the firm view that the best days for public health do not lie in the past, but in the future.

Index

Page numbers in **bold** refer to main sections of the text. Page numbers in *italic* refer to figures, tables and boxes. Since the major subject of this title is public health, entries under this keyword have been kept to a minimum, and readers are advised to seek more specific references.

Indexing style

Alphabetical order. This index is in letter-by-letter order, whereby hyphens, en-rules and spaces within index headings are ignored in the alphabetization.

Main abbreviations used

AIDS acquired immune deficiency syndrome
ANOVA analysis of variance
BMI body mass index
CJD Creutzfeldt–Jakob disease
COPD chronic obstructive pulmonary disease
HIV human immunodeficiency virus
SARS severe acute respiratory syndrome
STIs sexually transmitted infections
Other abbreviations are defined in the index
